ANNUAL REPORT OF THE COMMISSIONER OF PATENTS.

REPORT

OF

THE COMMISSIONER OF PATENTS,

FOR THE YEAR 1845.

February 24, 1846.

Read, and referred to the Committee on Patents.

Patent Office, *January*, 1846.

Sir: In compliance with the act of Congress, entitled "An act in addition to the act to promote the progress of science and the useful arts," approved March 3, 1837, the undersigned has the honor to submit his annual report, exhibiting the operations of the Patent Office during the year ending December 31, 1845.

The whole number of applications for patents received during the year 1845, is *twelve hundred and forty-six.* The whole number of caveats filed during the same time is *four hundred and fifty-two.*

The number of patents issued in 1815 is *five hundred and two,* including six re-issues, six additional improvements, and seventeen designs; classified and alphabetical lists of which, with the names of the patentees, are annexed, marked K and L.

During the same period *four hundred and seventy* patents have expired, a list of which is annexed, marked M.

There have also been eighteen applications for extensions, three of which only have been granted.

The claims embraced in the respective patents issued during the year 1845 are also hereto annexed, marked N.

The receipts of the office for the year 1845, including duties and fees paid in on applications for patents, caveats, re issues, additional improvements, extensions, and for copies, amount in the whole to $51,076 14; of which sum $8,223 33 have been repaid on applications withdrawn, and for money paid in by mistake, as per statement marked A.

The expenses of the office during the year 1845 have been, for salaries $15,545 20; temporary clerks, $4,097 09; contingent expenses, including postage, $8,224 58; compensation of district judge, $100; library, $813 04; agricultural statistics, $2,392 41; amounting in the whole to $31,172 32; leaving a net balance of $11,680 49, to be credited to the Patent Fund, as per statement marked B.

There has also been expended during the year past, under the act of

Ritchie & Heiss, print.

March 3, 1837, the sum of $2,938 75 for the restoration of records and drawings, and the sum of $593 58 for duplicate models, as per statement marked C.

The whole number of patents issued by the United States for inventions, up to January, 1846, is fourteen thousand five hundred and twenty-six.

The general business of the office, as well as its receipts, has, during the year past, greatly increased over that of any former year. The excess of applications over the number received in 1844, is *two hundred and one;* the excess of caveats filed during the same period, compared with the former year, is *seventy-two*, and the excess of receipts, $9,850 08. The statement hereto appended, marked D, will exhibit the progress of the business of the office from January 1, 1840, to December 31, 1845, inclusive, and will be interesting, inasmuch as it furnishes abundant proof that the march of improvement in the sciences and arts in this country continues to be rapidly onward.

The balance in the treasury to the credit of the Patent Fund on the 1st January, 1846, was $182,459 69, as will appear from the statement of the Register of the Treasury, and the note appended, marked E.

In accordance with the usage adopted by my predecessor, I have required of the two principal examiners, reports showing the progress of invention in this country during the past year, as they have been brought under the view of the Patent Office, which are hereto annexed, marked G and H. They are referred to as very favorable proofs of the talents and industry of those two officers, and as furnishing interesting reviews of the progressive march of the arts. It will be seen, by reference to those reports, that the past year has not been barren of valuable and important inventions and improvements; and that the inventive genius of our countrymen has suffered no abatement in the intensity of its activity, nor in the value and utility of its products.

In connexion with the scientific operations of the Patent Office, I will embrace the opportunity to state, that I have received from Professor Morse an interesting account of the different magnetic telegraphs now in operation in Europe, made up from materials obtained by personal examination, and which will be found in paper marked I. I am happy to add, that Professor M.'s own brilliant invention, by which thought is conveyed with the rapidity of the lightning's flash, is still pre-eminent over all others of a similar character now in use in Europe.

By the act of Congress of June 17, 1844, making appropriations for the civil and diplomatic expenses of the government, &c., the sum of $700 was appropriated for covering the coping of the Patent Office, and the further sum of $600 was appropriated for an iron railing on the portico and for lamp posts. The whole of the last mentioned sum was expended in the latter part of the year 1844, by my predecessor, and the work faithfully and substantially executed.

The sum appropriated for covering the coping was, after the work was commenced and nearly finished, found to be insufficient to complete it. Deeming it imprudent to leave it in an unfinished state, I directed the balance required to complete it, amounting to $59 07, to be charged to the contingent account of the office.

The Patent Office building is now in thorough repair, and will require no appropriation for the present year, to keep it in a state of preservation.

My predecessor, in his last annual report, deemed it his duty, in consequence of the great inconvenience arising from the increase of models, rendering classification almost impossible, and the transaction of the daily business of the office very difficult, to recommend the construction of one of the wings contemplated in the original plan of the building. The experience of the short time during which I have filled the office of Commissioner has convinced me of the necessity of an enlargement of the Patent Office building. The increase of the business of the office is not only rapidly multiplying the models of both patented and rejected inventions, but it imperiously calls for an addition to the examining and clerical force of the office. And, as the rooms at present appropriated to the reception and classification of the models, and the use of the clerks, are fully occupied, provision will have to be made for the latter, (if Congress shall authorize an increase of their number) as well as for the former. I would, therefore, respectfully submit, in view of the constantly and rapidly increasing business of the office, that provision should be made for the construction of both wings, agreeably to the original plan. One wing would be immediately occupied by the classified models, and the other would, in a few years, be necessary for the accommodation of the official corps of the office.

An estimate of the expense of erecting the two additional wings, made at my request, by a distinguished architect, is herewith submitted, marked F.

In connexion with the subject of the enlargement of the Patent Office building, I would respectfully call the attention of Congress to the necessity of an increase of the examining force of the office. The present board of examiners consists of two principal examiners, and two assistants. The last addition to the examining force was authorized by the act of March 3, 1839. By reference to the statement marked D, exhibiting the progress of the business of the office from January 1, 1840, to December 31, 1845, inclusive, it will be seen that the whole number of applications for patents during the first mentioned year was 765, and during the year 1845 they amounted to 1,246; thus nearly doubling in number since 1840, and since the last addition to the examining force was authorized. During the last year the number of applications has exceeded that of any former year, except 1844, *three hundred and ninety-nine*, and the number of caveats filed *one hundred and thirty-seven.*

The increase of the number of applications does not exhibit the actual increase of the business of the office. Each application adds to the labors of the examiners and clerks in nearly a quadruple ratio, as almost every case requires two or three examinations before it is decided, leading to more or less correspondence in relation to it.

The great addition to the number of new applications, during the two last years, has rendered it physically impossible for the examiners to keep up with the business of the office, even with the most arduous and persevering efforts, aided by the experience of years on the part of both of them.

An addition to this branch of the force of the office has, therefore, become imperatively necessary; and if it should not be made, the inventor must be subjected to long and unreasonable delay before his claims can be examined. The crowded state of business during the last year has already occasioned complaints and censures against the office, on the part

of impatient applicants, who were not apprised of the causes which prevented the seasonable examination of their cases. These causes were not to be found in the want of industry on the part of the examining force, but in the fertility of invention so creditable to our countrymen, which outstripped the physical capacity of the examiners to perform all the labors which were thus accumulated upon them.

When it is borne in mind that the Patent Office is wholly sustained by duties paid in by inventors—having, since its re organization in 1836, not only carried on its operations without aid from the treasury, but having each year contributed a surplus to the Patent Fund, a part of which is yearly appropriated for the collection of agricultural statistics and the purchase and distribution of seeds—it cannot be deemed unreasonable on their part that Congress will, with the money thus furnished by themselves, make every necessary provision for its continued efficacy and usefulness.

It is believed that the addition of one principal examiner and one assistant will be sufficient to enable the office, in the present state of its business, to perform its duties without unreasonable delay. But, if its business should continue to increase in the same proportion in which it has during the past two years, which is very probable, the addition to its force above recommended will not be long adequate to the performance of its duties.

Whether or not provision shall be made for any thing more than the present necessities of the office, is respectfully submitted to the wisdom of Congress.

In connexion with this subject, I feel bound to reiterate the recommendation of my predecessor, made in his last report, in relation to an increase of the salaries of the scientific corps of the office. The office of examiner of patents is one of the most difficult and responsible offices under the government. It requires the highest attainments in the sciences, and a soundly discriminating mind, to which may be added the most unquestionable integrity of character. An examiner should be a living encyclopedia of science, if the expression may be used. His multifarious duties require an intimate and thorough knowledge of the whole circle of science and art, together with a knowledge of modern languages—particularly of the French and German—and the most attentive and incessant mental labor. Yet, for all these high qualifications, and for labors scarcely second in intensity to those required by any officer in the government, the principal examiner is allowed only a salary of $1,500 per annum, and his assistant but $1,250. That it is wholly inadequate, as a compensation for such qualifications, must be evident to every one capable of appreciating the value of the talent and capacity equal to the duties required of an examiner of patents.

That it is not sufficient to retain the services of those capable of filling that place, this office has had proof in more than one instance. During the present year the office has lost the services of one of the most capable and efficient persons who was ever in its employment, and who was induced to resign by the inadequacy of the compensation which he received, and the more alluring prospects held out to him in other pursuits; and in filling the vacancies which have occurred by resignation and promotion in the examining department, since the undersigned has been at the head of the office, he has had to encounter the difficulty of securing

the services of persons of the requisite talents and attainments, in consequence of the total inadequacy of the compensation. He has had the mortification of being defeated, in his efforts to procure the services of suitably qualified persons, by a railroad corporation, which was able to pay more for such services than he was authorized by law to pay.

In urging an increase of the salaries of the examiners, the undersigned is happy to find himself sustained by the great body of the enlightened inventors of this country, who desire earnestly that the men who are to pass upon their valuable rights shall be not only men of integrity, but of the highest order of talents and scientific qualifications. They desire that the class of officers to whom the law commits their interests shall be capable of comprehending the many intricate and difficult questions submitted to them; and, as the Patent Office is sustained by a heavy tax on their ingenuity, they feel that it is due to them that a sufficient sum should be appropriated, in the form of salaries, to induce men of the requisite capacity to undertake the various and ungrateful duties of examiners.

For additional reasons in favor of an increase of the salaries of the scientific corps, I would respectfully refer to the last report of my predecessor, in whose views and recommendations on this point I concur.

The experience of this office, and the construction given to it by the courts, have proved that the existing laws are defective in many particulars; some of the most prominent defects in which I will proceed to point out.

1. In relation to the power of the chief clerk to act in the place of the Commissioner during his absence.

Under the second section of the act of July 4, 1836, it was believed that the chief clerk is clothed with the power to perform all the functions of the Commissioner, as well during his absence as when a vacancy existed in the office. Such, I understand, was the construction of the law by my predecessor, whose practice was in conformity to it. And, finding such construction and practice to exist when I entered upon its duties, I made no change in that respect. Recently, however, the correctness of that construction has been questioned by the United States district court in Massachusetts, and the authority of the chief clerk to perform the functions of the Commissioner during his absence denied. I also understand that this opinion of the court in Massachusetts is sustained by other eminent legal authorities. The practice may, therefore, be regarded as doubtful, if not wholly unauthorized by law.

If the construction and practice in relation to this matter be not correct, this office is placed in a situation of great inconvenience, inasmuch as in case of the sickness or necessary absence of its official head, its functions must, for the time being, cease.

The framers of the patent law, as the practice of my predecessor shows, contemplated no such result; and if they failed to provide for such a contingency, it was evidently because they did not duly weigh the meaning of the language which they used in the section of the law above referred to. To provide against the inconvenience and the evils which may result from such a defect in the law, some legislation will be necessary.

And, as the chief clerk has, since the reorganization of the office in 1836, officiated more or less as the acting Commissioner, and has signed many patents and other papers upon which important and valuable rights de-

pend, it is respectfully submitted if it is not expedient to make those acts valid by a declaratory law on the subject.

2. Some doubt has arisen in relation to the construction of the 13th section of the act of July 4, 1836, in relation to the power of the Commissioner to enlarge the claim of the patentee who surrenders his patent for correction and re-issue.

The 13th section provides "that, whenever any patent which has heretofore been granted, or which shall be inoperative or invalid by reason of a defective or insufficient description or specification, or by reason of the patentee claiming in his specification, as his own invention, *more* than he had, or shall have, a right to claim as new, if the error has or shall have arisen by inadvertency, accident, or mistake, and without any fraudulent or deceptive intention, it shall be lawful for the Commissioner, upon surrender," &c., to cause a new and complete patent to be issued.

On the part of many able jurists, who are thoroughly acquainted with the patent law, it is believed and contended that, under the section above quoted, the Commissioner has power to cause the issue of a patent only in cases where the patentee has claimed as his invention *more* than he was justly entitled to.

Such a construction of the provision in question would authorize the Commissioner to *limit* the claim of the patentee when he had claimed too much, but not to *enlarge it* when he had claimed too little; notwithstanding the new matter claimed, and to secure which the patent was surrendered for re-issue, was particularly set forth and described in the specification and drawings, and represented in the model.

Such a construction is in conflict with every sound principle of justice, and it should forthwith be remedied by an amendment of the law relating to this matter. It could not have been intended by the framers of the provision in question that the inventor should be deprived of the benefit of his invention, because, from inadvertence, mistake, or accident, he had failed *to claim* it all, notwithstanding he had set it forth in his specification, drawings, and model.

And, as the phraseology of the section of the act above quoted admits of doubt, it is respectfully submitted whether or not it is expedient to remove this doubt by additional legislation.

3. The next provision of the law in respect to the construction of which doubt has arisen, is that which relates to the degree and extent of the use of an invention, before a patent is obtained for it, which shall constitute an abandonment of it to the public.

Under the second section of the act of March 3, 1839, it has been held by the Patent Office that the sale or prior use of a machine within two years from the date of its invention was no proof of the abandonment of the invention to the public; and by that construction of the provision of the law referred to, both the office and inventors have, until recently, been guided.

It was believed that, upon a fair and liberal construction of the section referred to, if not by its very terms, the inventor is entitled to two years during which he might make experiments with a view to perfect his invention, or sell to others machines which he had constructed during that period, without invalidating his right to a patent.

But, recently, some of the judicial tribunals have been inclined to take a different view of that provision in the seventh section of the act of 1839,

and one of the circuit court judges, I have been informed, has, in one case, directly ruled, and so instructed the jury that the sale of a single machine is evidence of the abandonment of the invention to the public, and of course would destroy the validity of a patent issued under such circumstances.

It will be obvious that such a construction of the provision under consideration must greatly cripple the efforts, and, in many instances, the means of inventors. An invention does not, as did Minerva from the brain of Jove, spring from the inventor's brain perfect in form and action; on the contrary, it often requires years of painful thought and study, and numerous and varied experiments, to bring it to perfectibility. It also requires, oftentimes, a very considerable expenditure of money in constructing machines, and in making experiments. And as many, if not a large majority of that worthy class of men, are limited in their means, they find it a very great convenience, and sometimes absolutely necessary, to permit others to use publicly their machines, for the purpose of testing their perfectibility by experiment, and to sell them for the purpose of procuring the means to pursue their own experiments, and finally to obtain a patent.

In the judgment of the undersigned, nothing can be more just and reasonable than that the poor inventor should have the privilege of permitting others to use his machine by way of experiment, and of selling to others to use during the term of two years prior to his application for a patent, without invalidating his right to the same, supposed until recently to have been extended to him by the act of 1839. And it is, therefore, hoped that Congress will, by some further legislation upon the subject, clear the law of all doubt upon this point.

4. By the same section of the act of 1839, it is provided that every person or corporation who may have purchased any newly invented machine, manufacture, or composition of matter, prior to the application of the inventor for a patent, "shall be held to possess the right to use, and vend to others to be used, the *specific* machine," &c., so made or purchased, without liability therefor to the inventor, or any other person interested in the invention.

The Patent Office, believing that it was construing this provision according to its letter, as well as its spirit, has held that the right of the constructor or purchaser of a new machine, manufacture, or composition of matter, extended only to the specific and identical machine so purchased or constructed. By the judicial tribunals, however, it has been construed differently, and held that the constructor or purchaser, under such circumstances, not only acquired a right to use and vend the identical machine, or thing made or purchased by him, but also a right to the *invention* itself.

The effect of such construction of the provision referred to is, to give the constructor or purchaser of a machine, or other thing invented, a coequal interest in the *invention* with the inventor himself. It is obvious that, however loose and unguarded the language of the statute in relation to this matter may be, such a construction as that which has been given to it by the judicial tribunals could not have been contemplated by its framers. They could have contemplated no such injustice to the inventor, and it is therefore respectfully submitted if this provision does not also need amendment.

5. By the 18th section of the act of July 4, 1836, by which the Patent

Office was reorganized, provision is made for the extension of patents under certain circumstances for an additional term of seven years, and it is also expressly provided that "the benefit of the renewal shall extend to assignees and grantees of the right to use the thing patented, to the extent of their interests therein."

Under this provision, the board to whom the question of extension is submitted have heretofore held that the benefit extended as well to the assignees and grantees, as to the patentee. And this construction of the law has been sustained by some of the judicial tribunals, while it has been reversed by others.

In the eastern circuit, it was held by the late lamented Justice Story that the benefit of the extension *did not* extend to the assignees and grantees; and the distinguished Chief Justice of the United States has held just the contrary in the Maryland circuit, and sustained the construction given to this provision of the statute by the board of extension.

Already much litigation and consequent injury to both patentees and purchasers have grown out of this subject. A suit is now pending in the Supreme Court of the United States in relation to the well-known Woodworth's patent for a planing machine, involving very heavy pecuniary interests, in which this question is one of the points raised in the case. It is, therefore, a matter worthy of consideration if this conflict of opinion in the courts had not better be settled by the more speedy and less expensive process of legislation.

6. In all cases in which patents are refused by the Commissioner, the applicant, if he is dissatisfied with the decision of that officer, has two remedies, viz: one by appeal to the chief justice of the circuit court for the District of Columbia, and the other by a proceeding in equity against the Commissioner to compel him to issue a patent.

The 16th section of the act of July 4, 1836, and the 10th section of the act of March 3, 1839, which provide a remedy in equity for the aggrieved applicant, have failed to designate the place where these proceedings shall be had; and, consequently, the Commissioner may be harassed with suits in equity in every court of the United States having equity jurisdiction; at the same time subjecting him to the necessity of leaving his official duties at the seat of government at any time in order to attend personally to these proceedings. Suits may be pending at the same time in extreme parts of the Union, thus rendering it impossible for him to attend in person, if he should be required, as he is liable to be. No case has yet occurred in which the Commissioner has been compelled to attend in person; yet it would be best to guard against such a contingency, particularly as it is now held that the chief clerk has no power to perform the duties of the Commissioner in his absence, and the office would be left, in such an event, without an official head.

Two suits in equity are now pending against the Commissioner in the circuit court for the district of Pennsylvania, in which, as it has not been necessary for me to attend, I have employed counsel, and in one of which I have had the question of jurisdiction raised.

In the course of the administration of the office many other defects and ambiguities have been observed in the acts now in force, which it is now unnecessary to refer to; but if Congress should conclude to revise the present patent acts, (which I will take this opportunity to recommend,) they will, if required, be particularly pointed out.

In connexion with the revision and amendment of the present patent laws, I would remark that, in my judgment, some additions to the present enactments are necessary for the more effectual encouragement and protection of inventors and patentees.

The existing laws, while professing to give to the inventor the exclusive enjoyment of his invention for the term of fourteen years, do, in fact, afford to him but very little protection. The fruits of his genius and his toils are constantly liable to be wrested from him by the unscrupulous and dishonest, who, too often countenanced by public opinion, are apt to regard the rights of the inventor as the fruits of a monopoly which it is a merit instead of a wrong to break down and destroy; and the more valuable the invention, the more liable is the patentee to this species of invasion and injury, as there is more inducement held out to its perpetration. The stealthy thief and the midnight burglar are justly regarded as the pests and enemies of society, and are therefore seized and punished by penalties severe in proportion to the turpitude of their crimes; yet their depredations are committed on things which are made by law the subjects of property, and which may be acquired by industry or by purchase. The right of the inventor to his invention, in the judgment of all enlightened minds, cannot but be viewed as far more sacred than mere things of property. It is a mental creation, or rather the discovery of a principle or thing never before known to the world, and may be, and very many inventions have been, often productive of countless blessings to the human family, affecting their destinies as individuals and as communities through all time. When the wonderful discoveries of a Watt, a Fulton, a Whitney, and an Arkwright, and the great results to individuals and to nations which have followed from them, are contemplated, it is not difficult to realize the value of the splendid gifts which science, through their instrumentality, has bestowed upon man, nor to estimate the claims which the true inventor has upon society. He may truly be called the pioneer of civilization, the explorer of the unknown world of science and art. And yet how many of those truly great benefactors to their race have fallen victims to ingratitude and wrong, and gone down to their graves in penury and sorrow. The case of Eli Whitney, our countryman, the inventor of the cotton gin, is but one among innumerable instances in which the fruits of splendid genius have been wrested from its possessor by the unprincipled depredator upon patent rights. It is familiar to all that that great inventor, whose name stands out like a bright and lustrous star in the constellation of genius, was compelled to expend all the profits of his invention in fruitless efforts to protect it from infringement, and finally died a victim to debt and disappointment.

Many valuable inventions are now used in secret and kept from the world, on account of the impunity with which patent rights can be infringed, secrecy being a better protection to the inventor than the law.

These reflections are indulged in with a view to awaken in the public mind a proper estimate of the value of the toils and labors of the inventor, and of his claims to full and effectual protection in the enjoyment of the fruits of his genius and skill, and to enforce with more emphasis the suggestions which I deem it my duty to submit in relation to such amendments of the law as may be necessary for the security of the rights of inventors. The principal difficulties which the patentee has to encounter, under the present laws, in enforcing his rights, arise from two circum-

stances: first, from the fact that the question of originality may be raised on every trial for infringement; and, secondly, the almost total inefficacy of the existing law to prevent infringement.

In every application, the question of the originality of the invention is thoroughly investigated by the Patent Office; and as it is decided affirmatively or negatively, the patent is issued or denied. If the patent is granted, it is very properly (as the office cannot claim infallibility) deemed by the law only *prima facie* evidence of the originality of the invention, and of the right of the patentee to recover damages for an infringement of his claim. Yet there should be some point at which this question should be deemed as conclusively settled, and the right of the patentee to recover made absolute, or the patent declared to be a nullity. Yet, under the existing laws, such is not the fact; and although the question of originality may have been decided by twenty juries, in as many different trials, it is just as much open to dispute in all subsequent trials.

This difficulty in the way of the patentee to recover for infringements, in cases in which the invention is a very valuable one, and the infringer a wealthy corporation, amounts almost to an insuperable one, as he is kept in the law, and harassed by litigation, until the term for which his patent runs, expires; and he is left without adequate remuneration for his invention, and sometimes made poorer than when he commenced the fruitless attempt to vindicate his rights by an appeal to the law for redress.

In view of the inefficiency of the existing enactments upon the subject, to protect the inventor, I have deemed it my duty to recommend that the law should be so amended as to provide some process for the repeal of a patent within a limited period of time after it shall have been issued, in which all matters tending to invalidate it should be considered and forever settled.

The validity of the patent should be called in question only in this proceeding against itself; but in all suits by the patentee for infringements, the patent should be deemed conclusive evidence of his right to recover damages. Were such a provision incorporated into the law, it would compel all persons contesting the validity of a patent, to proceed in the first instance against the patent itself, in order to set it aside. And the courts would be relieved from an immense mass of litigation growing out of the disputed claims of patentees, and the patentees would not be subjected to the tedious and costly process of vindicating their claims to the invention patented, in every suit which they might institute for its infringement.

This proceeding against the patent itself, with the view of procuring its repeal, is not new in the legislation of other nations. It has for many years been the law of France, and has been found to operate beneficially, as well to patentees as to parties interested in the repeal of patents.

If it should be deemed expedient to engraft upon the present system a provision for the repeal of patents which may be invalid for any cause, the wisdom of Congress will devise such amendments to the existing laws as may be deemed necessary to effect the purpose.

In connexion with this subject, it may not be inappropriate to remark, that in all trials in which the validity of a patent may be involved the court should be aided by the counsel of persons learned and experienced in the art to which the patent relates. And particularly would this be expedient if Congress were to authorize a proceeding against the patent itself, for the purpose of effecting its repeal. The tribunal before which

the question should come should be constituted in part of persons learned in the art or science to which the patent relates.

Another obstacle in the way of full enjoyment, by the patentee, of the benefits of his invention, and which I have before alluded to, is the almost total inadequacy of the existing provisions of the law to protect him against infringement upon his rights.

By the 14th section of the act of July 4, 1836, courts are authorized to treble the damages awarded to the plaintiff by the jury, in their discretion. If this provision could be administered according to its true spirit and intent, it would probably afford adequate protection to the patentee. But long experience has shown it to be practically inoperative.

In the first place, juries, aware that their verdicts may be trebled by the court, sometimes take that circumstance into consideration in making them up, and do not award so high an amount of damages as they would if they were not conscious that their decision could be revised by the court; and courts, too, are reluctant in taking the responsibility of increasing the damages awarded by the jury.

Again: irresponsible persons are employed by others, who have adequate means to respond, to depredate upon the rights of the patentee, who has no remedy except against the ostensible perpetrator of the wrong, and against whom a verdict would be utterly valueless. It is not an uncommon practice for one person possessing capital to furnish to another, who has none, the means to manufacture an article protected by a patent; thus screening himself from the consequences of a prosecution, while he enjoys all the profits resulting from the trespass.

Machines protected by a patent are also operated in secret; and as the patentee has no legal power to enter upon the premises of another to ascertain whether or not his rights are invaded, and courts, upon trials, have not the authority to cause a view to be had of the machine and manufacture thus carried on in secret, the patentee is left, in such cases, entirely without redress.

To remedy these defects in the patent laws, and to afford to the inventor that full and complete protection which the law designed he should have, it is believed that the following additional provisions would be effectual, namely: that on all trials for the infringement of a patent, the question whether or not the infringement was knowingly and wilfully committed should be left to the jury; and if they should find in the affirmative, in addition to the damages which they may award, the courts should order that all the goods protected by the patent, together with the machines by which they shall have been manufactured, shall be forfeited to the use of the patentee, and the defendant be mulcted in double costs. This remedy, it is believed, would be much more efficacious than the existing one. Perhaps it would be expedient to add, by way of penalty, imprisonment on refusal to respond damages.

And in all cases where it is believed that machines are operated in secret, courts should be authorized to cause an examination of the premises, in order to ascertain whether or not the use of the machine is an infringement of the rights of the patentee.

By the 11th section of the act of July 4, 1836, the Commissioner was directed to charge the sum of three dollars for each assignment recorded in the Patent Office. This provision of the act of 1836 was repealed by

the 8th section of the act of March 3d, 1839, and now nothing is required for recording assignments. Since the passage of the last mentioned act, the number of assignments sent to the office to be recorded has multiplied so much as to require all the time of one clerk, and part of that of another, in recording and comparing them. During the year 1845, the office received 2,108 assignments, and for recording the same it paid out the sum of $1,018 95 to temporary clerks, besides appropriating more than one half of the time of one of the permanent clerks in reading and comparing the originals with the record.

As more than three-fourths of these assignments are sent to the office by speculators in patent rights, they should not subject the Patent Fund to be charged with the expense of recording them. This portion of the duties of the office is daily increasing; and it is believed that it would not be deemed unreasonable to require some return to the office, by way of a small duty, for each assignment sent to it for record.

The law now requires the payment of a duty of twenty dollars on the filing of each caveat. As this proceeding entitles the caveator merely to notice of all subsequent applications interfering with his invention, the duty is too high in proportion to the benefit derived from the caveat. Besides, there are many persons who have made valuable improvements in the arts which they are willing to bestow upon the world, but do not wish that other persons should obtain patents for things which they have not been the first to invent, or have not invented at all, and who would secure their use to the public by depositing in the Patent Office a caveat containing a description of the invention, if the duty were not so high. It is, therefore, suggested that a duty of ten dollars on the filing of each caveat, without permitting it to become, as now, a part of the patent fee, if it should be subsequently converted into an application, would be equally productive to the revenues of the office, and would also result in much benefit to the public.

The board provided by law to decide upon applications for the extension of patents is composed of the Secretary of State, the Solicitor of the Treasury, and the Commissioner of Patents. The very arduous duties required of the two officers first named, appertaining to their respective offices, render it very inconvenient for them to attend to the sometimes long and tedious examinations necessary in cases of applications for extensions. A board, composed of the Commissioner and the principal examiners, would, from the nature of their present duties, in the belief of the undersigned, be more appropriate; and it is suggested if it would not be expedient to abolish the present board, and transfer its duties to the Commissioner and examiners.

As an efficient performance of the duties of the Patent Office requires the extensive use of scientific works, many of which can only be obtained in foreign countries at considerable expense, the usual appropriation will be required for that branch of the office. I have found the library belonging to the office to be deficient in many valuable works, which the experience of the office has found to be very necessary, many of which are of a costly character, and cannot be obtained with the sum which may be left of the usual appropriation, after paying for the current periodical works and publications taken by the office.

As the office is now in an unprecedentedly flourishing condition, its revenues greatly exceeding its expenditures, it may be deemed expedient

by Congress to make a more liberal appropriation for the library than has been heretofore made.

An increase of the library, at present very incomplete, will contribute to the convenience of the scientific corps of the office, and give them increased facilities for the discharge of their duties, and is even more important to the inventors, to decide correctly upon whose interests it is very necessary that the office should know what has been done in foreign countries; a knowledge of which it can derive only by scientific works published abroad.

In most of the foreign countries in which rapid advancement is making in the arts, publications are from time to time made of new inventions, containing both descriptions and drawings, which are found not only to be of very great benefit to inventors and to the public, but which have been the means of rendering essential aid to the operations of this office. In this country there has been no such provision for the publication of patents; and consequently, for want of the information which such a work would give to inventors, machines and processes of manufacture are invented over and over again, to be as often rejected at the Patent Office, for want of novelty. In addition to the disappointment and mortification which applicants under such circumstances suffer, they often incur large expenditures in perfecting their inventions, and in their efforts to procure patents for them. Whereas, if descriptions of the new patents issued were once a year, or oftener, published, both the disappointment and expense of applicants would be avoided, and the office itself relieved of the labor and trouble of examining inventions which had long before been introduced into public use.

As this office is now in the possession of ample means, which are likely to be increased by its continually growing business, I would respectfully renew the recommendation made by my predecessor in his last report, that the Commissioner be authorized to subscribe for a thousand copies of some well established scientific publication, on the condition that it should contain quarterly (or oftener) descriptions and drawings of all new inventions patented during the year, which the Commissioner might deem it expedient to cause to be published.

The report upon agriculture for the year 1845, hereto annexed, and marked J, will be found to contain a large mass of matter valuable and interesting to the scientific as well as the practical agriculturist.

It will be perceived, from the review of the season which it contains, that, as a general fact, the crops have not equalled in quantity those of the preceding year. While the wheat crop has exceeded in amount the product of former years, almost all other important crops of the country have fallen short. That is pre eminently the case with the potato and hay crops of the northern and middle States, and of the corn crop in many of the southern States. The result is to be attributed to the cold and dry weather which prevailed in the northern and eastern States in the early part of the season, and in the middle and southern States in the summer. But, while some of the States have suffered from the causes just mentioned, others have been more favored than ever; and, on the whole, we have reason for gratitude to the Giver of all good, for the munificent abundance which he has bestowed upon our favored country during the last year.

The great range of latitude through which our country extends, commencing midway in the temperate zone and extending to the tropics, and

embracing almost every variety of soil and climate, secures to us, for our own consumption, a sufficiency of nearly every description of product which can minister to necessity or luxury, besides furnishing a large surplus of many valuable products for exportation to foreign countries, the returns of which, in the productions of the labor and capital of other nations, add to our individual enjoyment and increase our national wealth.

In truth, our agricultural products form the basis of our immense foreign commerce, thus constituting the strongest ligaments which unite us to the great brotherhood of nations; contributing not only to our national wealth, but to the cultivation of amity and peace in our foreign relations, and to the progress of civilization at home. In view of these beneficent influences, which have their origin in this great arm of our national industry, its flourishing condition cannot but be satisfactory and encouraging to the true patriot.

The report of this year will show that this great branch of national industry is not only extending with the rapidly increasing number of our population, but that agriculturists themselves are awaking to a consciousness of the importance of their noble avocation, and are calling science to their assistance in their efforts to improve.

In the analysis of soils, products, manures, and the food of cattle and other stock, chemistry has already conferred immense benefits upon the agriculturist. Other sciences are also bestowing their valuable donations upon him. Nor is the inventor behind in this work of cherishing the agriculturist. His genius adds its splendid gifts to the rich charities of science, as will be seen by the numerous and valuable machines which have been devised and constructed to relieve the toils and facilitate the labors of the husbandman. The names of Eli Whitney, the inventor of the cotton gin, and Jethro Wood, the inventor of the cast-iron plough, will be ranked among the greatest of benefactors while man is doomed to earn his daily bread by the sweat of his brow.

In this branch of my labors I have been aided by the contributions of many distinguished friends of agriculture, whose communications will be found in the appendix to the agricultural report. And, among others, I have received several valuable papers collected by my late predecessor, the Hon. H. L. Ellsworth, and one from his own pen, relating to prairie cultivation, which will be found very interesting, and to which I would particularly refer, as containing much valuable knowledge derived from experience upon a subject of great interest to the government as well as to individuals.

Among other valuable papers furnished by Mr. Ellsworth, is a translation of an abridged French treatise upon the cultivation of the colza plant, by J. W. P. Lewis, esq., of Boston. The colza is a species of the cabbage, and is cultivated in France for its seed, which contains extraordinary oleaginous properties, and from which large quantities of oil are manufactured, of a quality for lights nearly equal to the best sperm, and which is now used in the different light-houses of that kingdom. Through the aid of Mr. Lewis, Mr. Ellsworth has also favored the office with a small quantity of the seed of both the summer and winter colza, which has been distributed to the members of Congress.

The potato disease, which has made such ravages in this country and in Europe during the last two years, has formed a prominent subject of

careful investigation, the results of which will also be found in the agricultural report, together with many valuable papers relating to that subject.

Of the last appropriation for agricultural purposes, I have expended nearly $1,000 for seeds of various kinds, and for preparing them for distribution, samples of each of which have been distributed to members of Congress. The number of packages distributed this year will exceed 50,000.

When it is considered that only $3,000 is appropriated for agricultural purposes, and one-third of that sum is appropriated for seeds, and much of the remainder expended for the mere copying of the report, it may justly be deemed a matter of surprise that such a mass of interesting matter has been collected and embodied as will be found in the agricultural report of this year.

It has been accomplished only by the most rigidly careful expenditure of the fund placed at the disposal of the Commissioner. In discharging this part of my duty, I have severely felt the want of sufficient means to collect important information for the purpose. And I am compelled to acknowledge, that without the kind and generous contributions of intelligent citizens devoted to the interests of agriculture, it would be impossible for this office to collect and to lay before the country so many interesting facts, and so much valuable information, in relation to the interests of this great and paramount branch of national industry.

If the Commissioner were provided with more ample means, the theatre of his operations in this branch of his duty could be greatly extended. At present the office has no means for making inquiry into the improvements of agriculture in foreign countries, nor for collecting rare and valuable seeds abroad. I am gratified in having it in my power to state that our consuls and other agents residing in foreign countries, evince great willingness to aid this office in its efforts to advance our agricultural interests at home, by the collection of valuable information and seeds in the countries in which they reside; but I have not been able to avail myself of the services of gentlemen holding official stations abroad, proffered in numerous instances, for want of the necessary means to defray the expenses of the purchase of seeds and their conveyance to this country; and thus are our agriculturists not only deprived of an early knowledge of the advance of the science of agriculture in other countries, but also of seeds which, in our extended country, would find a soil and climate congenial to their nature and habits, and would add much to the elements of national wealth.

During the present year, I have availed myself of the services of a very intelligent gentleman, formerly connected with this office, and now travelling in Europe, in collecting agricultural information in the different countries which he may visit. Those services were voluntarily tendered. If compensation had been required, I of course could not have availed myself of the services of the gentleman referred to, because I had not the means to meet the demand. Two valuable communications have already been received from that gentleman, which will be found in the appendix to the agricultural report, and much more is expected, which may not arrive in season for the present report.

When it is considered that much of the legislation of Congress, and millions of the treasure of the nation, are devoted, in one form and another, for the protection of manufactures, commerce, and other interests, it would

not seem unreasonable if a few thousands should be annually appropriated for the promotion and advancement of that greatest and most essential of all the interests of the country—the agricultural. The farmers themselves, while they cheerfully pay the millions of taxes demanded of them for the support of other interests, would not complain if a few thousands were added to their burdens for the promotion of their own.

If Congress should come to the conclusion to increase the means at the disposal of the Commissioner for the purpose above suggested, it would enable him not only to add much to the value and usefulness of the agricultural report, but to add new varieties to the different grain and vegetable crops now produced in the country.

In connexion with this subject, I deem it proper to remark that the sum now annually appropriated for agricultural purposes is taken from the Patent Fund, all of which has been paid into the treasury by the inventors, and which has been set apart by law for the promotion of the useful arts, and for the benefit of that class of citizens from whom it has been collected. They justly complain of this misapplication of the Patent Fund, and demand that it shall be appropriated to the increase of the efficiency of the Patent Office. I concur entirely in the justice of their complaints, and respectfully submit if it would not be expedient to apply the revenues of the office to the increase of its force, and to the objects to which, in a preceding part of this report, I have called the attention of Congress, and make the necessary appropriation for agriculture from other moneys in the treasury.

It was suggested in the last annual report of my predecessor that provision should be made for a permanent clerk, to aid in procuring the statistical information for the agricultural report. In the discharge of my duties in connexion with that subject, I have found that the services of a competent clerk are greatly needed. The numerous other duties devolving upon the Commissioner render it physically impossible for him to attend entirely to this portion of the business of the office, and he is obliged to require the labors of the regularly employed clerks in that department. It requires nearly the entire time of one clerk to read the domestic and foreign publications on agriculture, in order to make the necessary selections of matter for the report; and those services, which require sound discrimination and judgment, are paid for out of the sum placed at the disposal of the Commissioner for agricultural purposes, in the expenditure of which he has a very general discretion. Translations from foreign publications and works are also required, which are paid for out of the general agricultural fund.

It is therefore submitted if it would not be expedient to establish a permanent clerkship connected with the agricultural duties of the office, the salary of which should be adequate to command the services of a person skilled in statistics, and acquainted with foreign languages. It might be taken from the general sum appropriated for agricultural purposes, and would not add to the expenses of that branch of the office.

The object of the report on agriculture is to show the general progress of that branch of national industry, and the particular amount of agricultural products, so far as it is possible for the Commissioner, with the limited means at his command, to approximate to exactness and precision in his estimates of the crops.

In procuring materials for the report, he is compelled to rely on agricul-

tural publications, the voluntary contributions of intelligent and public spirited citizens, and the returns which he solicits from members of Congress. The means which he possesses for procuring accurate and reliable information are, therefore, very limited. With suitable legislation on the part of the several States of the Union, they might be made ample. If the legislature of each State were to require returns to be made annually of all its agricultural products, the results of which to be transmitted to the Patent Office, the Commissioner could furnish to the country, each year, a full and complete view of its agricultural products, and of the general progress of that branch of national industry. This information could be very readily obtained through the medium of the assessors of the taxes in the several towns and districts of a State.

Some of the States now require returns of the kind to be made by their assessors at certain periods. Much assistance in making up the agricultural report for the last year has been derived from the returns of the late census of the State of New York.

It is, therefore, hoped that the legislatures of the different States will turn their attention to this subject, and make provision for the collection of the statistics of all branches of industry, and direct the information thus obtained to be communicated to this office.

In addition to other useful matter, I have appended to the agricultural report the annual reports of the Liverpool cotton, corn, tobacco, provision, and wool markets, for 1845, together with tables showing the importation, exportation, consumption, and manufacture of cotton in Great Britain for a series of years. The statistical information which the tables furnish will be interesting to one section of the agricultural interest, and useful to the statesman and legislator.

As the Patent Office is now regarded as the general head and representative of the useful arts and the industrial interests of the country, it might be employed in collecting the statistics of all the great branches of national industry—agricultural, manufacturing, commercial, and mining.

Without knowledge of this character a nation knows but little of its capacity, its resources, or its power; nor without it can the legislator perform his duties, in relation to the great interests of his country, with that sound wisdom and judgment which the importance of his position and the consequences of his official action, good or evil, demand.

In almost every other enlightened nation great attention is paid to the procuring of the most copious statistics in relation to all its interests. In this country, it must be confessed, they are comparatively very meagre.

With suitable action on the part of Congress, aided by the co-operation of the several States, this desideratum might be supplied, and the mighty resources of our country become known as they are developed.

In the absence of the action of Congress and the State legislatures upon the subject, it is desirable that voluntary associations of citizens should be formed in the several States and districts of the Union, with a view to the collection of statistical knowledge of all kinds. Much might be gathered in this way, and embodied for public use in the annual reports of this office. Already numerous agricultural societies and clubs have been formed in different portions of the Union, from whose labors and efforts this office has derived much assistance. Their efficiency and usefulness would be increased in proportion to their numbers, and the

judgment and energy with which they should pursue the purposes for which they may be instituted.

The great hall of the Patent Office, known as the national gallery, was designed for the exhibition of works of art, new and curious machines, unpatented as well as patented, and specimens of the manufactured fabrics and articles of this country. At present this design is partially frustrated, by the occupation of the room as a place of deposite for the valuable and interesting specimens of natural history brought home by the exploring expedition.

It is not recommended, nor desired, that those specimens should be removed. On the contrary, it is believed to be best that they should remain in the Patent Office, as they increase the interest of visitors to this noble institution of our government, and extort admiration from those coming from foreign countries. By the latter, the Patent Office, with its rich and varied contents, is justly deemed an honor to the republic.

But, if Congress should deem it expedient to increase the Patent Office building, by erecting one or both of the wings contemplated in the original plan, there would be sufficient room for the exhibition of valuable specimens of manufactured fabrics and mechanical ingenuity. And I cannot doubt that the ample room which would be provided for them would be speedily filled by the choicest specimens of the skill of our ingenious artisans. Such a collection would be as honorable to the nation, as it would be creditable to those who produced them.

All which is respectfully submited.

EDMUND BURKE,
Commissioner of Patents.

Hon. John W. Davis,
Speaker of the House of Representatives.

A.

Statement of receipts for patents, caveats, disclaimers, improvements, and certified copies, in 1845.

Amount received for patents, caveats, disclaimers, and improvements - - - -	$49,700 00	
Amount received for copies - - -	1,376 14	
		$51,076 14
Deduct paid on withdrawals, and money paid in by mistake refunded - - - - - - -		8,223 33
		42,852 81

F.

Estimate of the expense of constructing the two wings of the Patent Office building, by Robert Mills, Esq.

Sir: Agreeable to your request, I have the honor to make the following statement in relation to the plans submitted for your consideration of the proposed additions to the Patent Office building:

1st. *On the estimates.*—The east and west wings, each 100 feet deep and 70 feet front, made thoroughly fire-proof, and to correspond in their architecture and material with the present building, will cost $150,000

Or the west wing, which has an extra story	$80,000	
The east wing	70,000	
		$150,000

The accommodations provided in the west wing will be—

1. A roomy cellar under the basement story;
2. A large room for a lecture hall, 94 feet long, 64 feet wide, and 15 feet high;
3. A spacious model room above this, or on a level with the portico floor, of the same size;
4. A similar sized room above this, with a gallery running all around the whole height to the roof, which will furnish an uninterrupted surface of wall of equal extent, for the exhibition of paintings, lighted from above.

The east wing will furnish the same accommodations, save the cellar story.

Entrances are provided to each wing from 7th and 9th streets, and stairways to ascend to the upper stories, without having to use the main entrance and stairway.

If an early appropriation could be obtained for the execution of either or both of these wings, one or both could be put under roof before the working season closed.

Respectfully submitted:

ROBERT MILLS, *Architect.*

Hon. Ed. Burke,
Commissioner of Patents.

G.

Report of Charles G. Page, examiner, &c.

Patent Office, *January*, 1846.

Sir: In conformity with your requisition, I have the honor herewith to submit the following notice of inventions patented during the past year.

Since the commencement of the year 1845, the whole number of applications presented to the office is 1,246. Of these, 729 have been apportioned to me for examination; 291 of the 729 have been patented; the remainder have either been rejected or are still pending, waiting final examination. The subjects of applications for patents are comprised under 22 general classes or divisions; each of these comprehending a number of subdivisions, and in some cases more than 20.

Twelve of the above classes are assigned to me for examination, and are as follows, viz:

1st. Agriculture, including instruments and operations.

2d. Chemical processes, manufactures and compounds, including medicines, dying, color making, distilling, soap and candle making, mortars, cement, &c.

3d. Calorific, comprising lamps, fireplaces, stoves, grates, furnaces for heating buildings, cooking apparatus, preparations for fuel, &c.

4th. Mathematical, philosophical, and optical instruments, clocks, chronometers, &c.

5th. Hydraulics and pneumatics, including water-wheels, windmills, and other implements operated on by air or water, or employed in the raising and delivery of fluids.

6th. Lever, screw, and other mechanical powers, as applied to pressing, raising, and moving weights.

7th. Stone and clay manufactures, including machines for pottery, glass making, brick making, dressing and preparing stone, cement, or other building materials.

8th. Leather, including tanning and dressing, manufacture of boots, shoes, saddlery, harness, &c.

9th. Household furniture, machines and implements for domestic purposes, including washing machines and cracker machines, feather dressing, &c.

10th. Arts, (polite) fine and ornamental, including music, painting, sculpture, engraving, books, printing, binding, jewelry, &c.

11th. Surgical and medical instruments, including trusses, dental instruments, bathing apparatus, &c.

12th. Wearing apparel, articles for the toilet, &c., including instruments for manufacturing.

CALORIFIC.

Number of applications, 120.—Number of patents granted, 62.

Considering the large proportions of applications under this head, the novelty of invention presented has been less, perhaps, than of any other class. The subject, one would suppose, has been nearly exhausted; and

it is probable that but few advances of intrinsic value will be made, until some fortunate inventor shall strike out a new path for exploration. The discovery of new sources of heat and light must be made, to give stimulus to inventive effort in behalf of this now overburdened class of inventions. Thus, improvements in lamps were nearly at a stand, until the camphine, or pine-oil, or lard, or some other combustible material, was substituted for oil; and, as each of these sources of light required distinct and peculiar contrivances to render them applicable, so from each was opened up a new track for investigation, experiment, and invention. It is by such process that the field of invention is ever widening, and *will* ever widen till the limits of time shall fix its boundary. Since the establishment of the Patent Office there have been issued 800 patents for stoves, and 130 for improvements in lamps. Doubtless there have not been as many distinct claims to novel inventions, as patents granted; for, prior to the recent organization of the office, patents were frequently granted more than once for the same inventions. But, notwithstanding the swollen list of patented stoves, genius has been fruitfully exercised during the past year upon this useful article, in some cases producing inventions which, from their excessive complication, bore full title to novelty and originality, and, in others, where the novelty was scarcely perceptible at first sight, from the simplicity of the invention, but in which the real merits of economy were conspicuous. To use a paradoxical phrase, it is very easy to invent a stove which will *save all the fuel;* but to combine simplicity of construction, ease of management, and economy of fuel, is no easy task. A stove of this last description has been invented during the last year, in which, by the simple position of what is termed a reverberating plate, much that is desirable has been presented in a single and cheap stove. Much has been done in the line of cooking-stoves and ranges; and all the varieties of cooking may now be performed simultaneously, and with a single fire, and small expenditure of fuel. The question has been raised by some, and not without merit, as to the real economy of protecting an almost endless variety of cooking and other stoves; for the trial of some half dozen, before one can be found suitable for the purpose, and the destruction, in a few years, of the best articles of the kind, (that is, in many cases where the want of provision for the unequal expansion of the plates cracks and spoils the whole fabric in a short time) has led some to the conclusion that the economy of the stove is specious and deceptive, and that the fireplace is, after all, the most profitable in the end. The vast number of rival stoves presented to the public does, indeed, often place one in such a dilemma; but, on the whole, it is desirable at least that those capable of judging in such matters for themselves should have an extensive range for selection.

Under this class has been patented a simple and valuable improvement in the hatter's kettle, which gives a large heating surface to the kettle, prolonging the draught and saving much heat, by making the *smoke-flue* to serve, by a simple contrivance, the purpose also of the *stoke-flue.*

In air-heating stoves, furnaces, and other apparatus for warming buildings, considerable improvement has been made; but, in general, the inventions have not been characterized by much originality of device or principle. In hot-air furnaces for warming dwelling-houses and other buildings, an improvement has been patented which obviates a great inconvenience existing in most fixtures of this kind. The furnaces, to be

kept in order, must be taken down and cleaned once, and frequently twice, every year; which operation, from the great weight of the parts, and difficulty of resetting, is one of great trouble and expense. The flue passages become lined with soot, which not only obstructs the draught, but intercepts the heat. In the improvement spoken of, the flue passages have external openings passing through the walls of the arch or hot-air chamber, and surmounted with a cap or door. By removing these caps the flues are accessible throughout; and thus, if the furnace be properly jointed when first set, there is no necessity of afterwards disturbing the flues.

Lamps.—An invention of some utility, as applied to lamps, has been patented, affording a ready means of controlling the height of the flame without raising or lowering the wick, and giving in fact a greater amount of available light, without increasing the consumption of the oil. It consists in the application of a register-valve to the drip-cup of Argand lamps, more particularly those known as the solar lamp. In most of the lamps of this description, the holes admitting the interior draught, placed usually around the drip-cup, have been made of sufficient size to admit air enough to supply oxygen for the perfect combustion of all the carbon at the ordinary height of the wick. If the draught be lessened by contracting the size of the holes, the effect will be to raise the flame higher above the wick, causing a less perfect combustion of the carbon. But it may be so regulated in this particular that all the carbon may be consumed, though at a considerable height above the wick; and the effect of such extension or dilatation of the flame is to extend the radiating surface, and thus the real luminous effect in an apartment is enhanced, as may be readily proved by the ordinary photometric tests. As the wick is not raised in this case, and the amount of combustion is the same as with a greater draught and lower flame, it follows that the saving is real; and the invention further recommends itself from the facility it affords of regulating the light without the necessity of handling a highly heated part of the lamp.

Considerable progress has been made in the camphine or pine-oil lamps, as regards their cheapness and safety—the highly combustible material being so remote from the burning point as to be kept cool, and thus obviating all danger from explosion, which was of frequent occurrence before the improvement was introduced. The only danger that can now arise from the use of such lamps is from fracture and extensive spilling in contact with flame. This lamp possesses one important advantage, viz: that of giving a white light, more nearly approaching the light of day than that derived from any other lamp. A pale straw color is distinguishable by the camphine light, which is not the case with oil, lard, or gas light. It has its drawbacks in the occasional derangement of the wick or button, by which a copious sooty deposite forms, covering and soiling furniture, dress, &c.; in the unpleasant odor of turpentine pervading the apartment, and the slight chance of danger from fire. It, however, at the present high price of the liquid, is cheaper than oil. It may be well to remark, that the terms camphine and pine oil are synonymous, both preparations being highly rectified oil of turpentine. The introduction of private gas establishments, for the purpose of illumination, has been successfully made during the past year in several parts of our country; and, although careful and extensive experiments in England, made upon this subject, have resulted in placing attempts to substitute oil and resin for coal, in the

production of gas, as one of the follies* of ignorant and hasty speculators, yet the perseverance of humble experimenters in our own country has resulted in the adoption of both these substances, under peculiar circumstances, as economical sources of carburetted hydrogen gas. In the western country, where lard is so abundant and cheap, the refuse fats of the kitchen alone have been found sufficient to supply large establishments with oil gas. One of the peculiarities in the process there adopted is the introduction of a small proportion of atmospheric air along with the gas, which has been secured by letters patent.

One of our light-houses has for some time been lighted by gas from resin, and, I believe, with approbation. The process which has been patented is about to be adopted in one of the largest hotels in this city—the preparations therefor being nearly complete.

In no one branch of domestic economy has greater progress been made than in the construction of lamps, as regards their price. Argand or solar lamps, adapted to the burning of lard or oil, but more especially designed for lard, are now afforded for the very low price of two and a half and three dollars. For this sum a handsome table lamp, with a round glass globular shade, a glass chimney, and one dozen wicks, may be purchased at retail.

The benefits to the public, arising out of the act authorizing the grant of letters patent for designs, have been specially evident in works belonging to the above class. The protection of new and ornamental devices in stove castings has enabled the manufacturer to go to considerable expense in preparing ornamental patterns for his stoves and parlor grates, and the same time to afford them at a very moderate price. The consequence has been that we are supplied with a rich variety of cheap ornamental iron work; and our furnacemen, if they have not already, will soon rival the beautiful Berlin castings.

AGRICULTURE.

Number of applications, 133.—Number of patents granted, 48.

But little novelty has been presented to the office in the way of agricultural implements; and although the subject is one of fast growing interest and value, and has received some rich contributions from chemists and philosophers, yet those branches usually coming before the office have not received as many accessions as in former years. Some improvements have been made in ploughs, particularly wheel ploughs; several new devices have been patented, and one new and apparently valuable invention for adapting the set and draught of the plough in a ready manner, so as to take more or less land, at pleasure.

The *bee hive* has been the subject of much attention; many of the hives presented, exhibiting only changes of form, without the attainment of any new principle in bee management. It is believed that no effectual means have yet been discovered of preventing the ravages of the bee moth, independent of constant personal attention; although several of the inventions patented for this purpose will doubtless, to a considerable ex-

* See Ure's Dictionary of Arts, &c.

tent, diminish the evil. In spite of all the artifices to decoy the moth into traps and to deposite its eggs where the grub will be so remote from the entrance to the hive as to perish in the attempt to reach the comb, this insect retains enough of its instinct to enter as it is wont, with the bee, and deposite its eggs directly in the comb, even in the uppermost part of the hive. As the moth exists only at certain seasons, and does its work only at night, it follows that the entire enclosure of the hive at night will exclude the enemy with certainty. For this purpose the hives are sometimes arranged under a tightly-jointed house, provided with ventilated doors of wire gauze, which are shut regularly at night and opened early in the morning. The objections to this plan are, the expense of the fixture, and the unfailing attention required to open and close the doors; for a single act of neglect in this duty might result in the destruction of the hives. A curious invention has been patented, worthy of mention in this connexion. The patent was granted for combining a hen roost in such manner with the door of the hive that the weight of the fowls going to roost would operate, through the medium of levers and pulley, to close the door of the hive, and the door opened by reverse action in the morning when the fowls leave the roost. If, as the inventor asserts, he can depend upon a certain number of his fowls retiring and rising with the bees, it will prove a valuable labor-saving invention.

HYDRAULICS.

Number of applications, 34.—Number of patents granted, 17.

This class, which has been apportioned to me for examination during only a part of the past year, has embraced a large number of applications, particularly in the subdivision of water-wheels. As usual, they have exhibited much variety, but in which it has been difficult to detect much variety or novelty of principle. Changes and contortions in the forms of the buckets have been the leading features, although several of them have displayed novelty and peculiar fitness for certain situations and kinds of work.

The ancient and too long neglected *water ram* has, during the past year, been revived under new phases, and, it is believed, with good success. The syphon ram has long been known—that is, a ram in which the descent of water in the long leg of the syphon has been made to operate in raising, or rather delivering water above its level. But, so far as known, it has been a philosophical toy, and unavailable for practical purposes. By the intervention of a rarified air chamber, as it is called, in conjunction with the momentum of the descending water in the long leg, the syphon ram has been made an attainment of much practical value, and possesses the advantage of being more simple, cheaper, and less liable to derangement than many of the devices employed to raise water above the level of its source. In this instrument the water employed to operate the ram is the same as that which it delivers above the source; but another patent has been granted for a double ram, in which the force of a running stream or branch water has been employed to raise spring water to any desired height. In this ingenious instrument the two kinds of water commingle to a certain extent, but not in such a manner as to vitiate the spring water in the slightest degree.

STONE AND CLAY, &C.

Number of applications, 16.—Number of patents granted, 9.

Inventive genius has been but little directed to this branch of art in this country for several years past, while it has received much attention abroad.

It has been asserted, in some public journals, that the wonderful and lost process of Sagatto for petrifying animal substances has been rediscovered in this country, and a patent granted. No application has been made to the office for letters patent for such an invention. It is asserted that the process has been a third time discovered in Italy, it having been twice made and perished with the authors.

A patent has been granted for an improved mastic, which cannot be better described than in the words of the patentee: "What I claim for my invention, and desire to secure by letters patent, is, the substitution of red sandstone and clay, reduced to a powder in their natural state, or argil, silex, and the oxide of iron, for the stone of Sessyl or Val du Travers, or other assimilated materials, in combination with the mineral tar of Sessyl, or with any other bitumens used in the formations of mastics."

WEARING APPAREL.

Number of applications, 24.—Number of patents granted, 7.

A large number of applications have been made for patents for systems of cutting garments, and rejected, as not presenting appropriate subjects for letters patent. The mere selection of points of admeasurement, or the multiplication of such points, usually constituting tailors' measures, have not been considered as inventions within the meaning of the law.

An important invention has been made in the manufacture of buttons, which much facilitates the construction, and greatly improves the button for wear and use. The claim of the patentee is sufficiently descriptive of the character of the invention. "What I claim, is my improvement in the modes usually adopted for making the eyelet holes or thread passages of buttons, composed of two circular plates of metal, the one of said pieces being confined to the other, as above described; the said improvement consisting in punching holes through the plates (so as to leave a bur projecting on one side of the plate from each hole) before they are applied and connected to each other, and (in combination with) applying the said holes of one plate to those of the other in such manner that their burred projecting edges may be in direct contact, and the countersunk portion of each of the holes of the plate (there being the same number of holes in each plate) be opposite to that of the corresponding hole of the other plate, thereby forming eyelets or passages countersunk on both sides of the button; by which mode of constructing, the above wear of the threads which secure the buttons, when sewed to the cloth or other material, is, to a very great degree, obviated.

HOUSEHOLD FURNITURE.

Number of applications, 31.—Number of patents granted, 14.

But few improvements of a patentable nature appear to have been made in this branch of domestic economy.

A very simple and useful invention for a revolving pivot chair, or stool, has been patented, which is designed chiefly for the use of schools. It answers also for other purposes, and its construction is of such a character as to render it very economical and durable. In pivot chairs, such as piano stools, &c., hitherto the point of suspension, or centre of motion, has been in the centre of the seat of the chair, and liable to be overturned with the sitter. In the new chair this pivot is eccentric, and is ascertained by observation and calculation with reference to the centre of gravity of the person, securing greater firmness to the sitter.

Castors.—Very many attempts have been made to obviate the difficulties attendant upon the use of castors for furniture, and many of the contrivances have been so complicated and expensive as to preclude their general introduction. The defects are chiefly friction upon the pivot of the castor preventing freedom of motion, a want of strength in the parts sustaining the greatest pressure, and difficulty of repairing when broken. A patent has been re-issued for one of these useful articles, which seems to present all the proper requisites, and great simplicity. It is a simple stout castor, with a long spindle or shank inserted in a deep hole in the leg of the chair or bedstead, without fastening; when the chair or bedstead is raised from the floor, the castor, of course, drops out; but the advantage of this is obvious, when we consider how many injuries have been inflicted both upon the person and furniture where fixed castors have been attached to heavy articles of furniture, such as bedsteads, by leaving the detached parts of the frame to stand upon two castors, the slightest jar being sufficient to throw them down. The hole in the leg of the chair or other article may be bushed with metal, as circumstances may require.

SURGERY.

Number of applications, 40.—Number of patents granted, 19.

The records of the office cannot be taken as a criterion of the progress in this class of inventions, for very many of the most valuable improvements in surgical instruments are of limited use, and are made by those who can afford to give their improvements to the profession for no other compensation than the award of increased reputation. Many unsuccessful applications have been made for patents for medicines professing to be infallible cures for various diseases. Without attempting to discourage the efforts of ingenuity in the healing art, I may be permitted to say that the most rigorous investigation and exercise of your discretionary powers have been directed to the decisions of such applications.

A patent has been granted for a substantial improvement in dental instruments, in which the advantages of the old turnkey have been combined with those of the forceps. In the turnkey, as before constructed, the hook was to be fixed under the tooth by the insertion of the finger, or by some mechanical contrivance of an unmanageable nature. In this instrument the forcep's handles are so combined with the hook of the turnkey as that the opening and closing of the handles controls the movements of the hook, and fixes it at the pleasure of the operator, saving the necessity of introducing the finger in the mouth.

An artificial nipple has been the subject of letters patent. Its construction is novel, and has evidently been the result of close observation upon the philosophy of nursing. Most of the instruments hitherto used for

this purpose have failed, not only from the unfitness of the material used, but from the want of proper attention to their construction. The description of the inventor is as follows: "The artificial nipple, in figure and dimensions, resembles other devices of the kind, being made conical, with the wide end open, the edge being shaped so as to press upon without injuring the breast. The small end is closed, with the exception of a minute perforation in the centre. The material around the perforation projects so as to form a tube of about one-eighth of an inch in length, over which is attached, by ligatures of silver wire, a tube of India rubber, about half an inch in length. This last tube is constructed of a flat piece of India rubber, cut square at one end and conical at the other. It is then perforated through its thickness in the direction of its length, so as to leave a slit on its upper end, and the lower end having an opening large enough to fit upon the projecting part of the nipple."

Another improvement has also been made in the material of this instrument, the nipple being made of the elastic portion of bone, the earthy parts having been removed by chemical process.

Patents have been granted for several species of exercising machinery, designed to furnish invalids, who are confined within doors, with regular and pleasing exercise.

A few patents have been granted for abdomen supporters and trusses for hernia; and although some of the improvements seem to possess intrinsic merit, yet there does not appear to be much that is strikingly novel in this branch.

An improvement has been added to a patent for a galvanic instrument designed to remedy constipation by the stimulating influence of the galvanic fluid upon the rectum. The instrument consists of a tube of silver and zinc, being separated by some non-conducting material. The use of the instrument is affirmed to produce a purgative effect in a gradual manner, but with certainty. The improvement consists in the manner of making and breaking the galvanic circuit with ease and rapidity.

FINE ARTS.

Number of applications, 40.—Number of patents granted, 32.

An ingenious device in machines for ruling paper has been patented by which the ruling may be stopped at any desired distance from the edge of the paper, the edge of the paper itself performing the part of a cam, operating to raise the pens from the paper at any desired point. The thickness of a sheet of paper is a very slight thing to depend upon for operating machinery, but there is no doubt of the successful operation of the invention, as the model furnished the office, though imperfect, demonstrated the fact.

Writing machine.—A very elaborate machine for writing has been patented, evidently the fruits of deep study; and, in view of the complexity of results produced by this contrivance, the construction is exceedingly simple, as well as its operation. The object of the invention is to furnish to those who are unable to write, the means of writing, by sitting before a set of keys, the mere touching of which immediately causes the corresponding letter to be written upon a sheet of paper. A set of cams, one for each letter, are made to operate upon the pen, so that all the rectilinear and curved movements necessary to make the letters are readily and neatly

NORWICH 3. FEBRUARY 1846

GENT.

WE HAVE, AT LENGTH COMPLETED ONE OF THURBERS MECHANICAL CHIROGRAPHERS. ALTHOUGH YOU WILL NOTICE IMPERFECTIONS IN THE FORMATION OF THE LETTERS IN THIS COMMUNICATION, YET THERE IS NOT A SINGLE DEFECT WHICH DOES NOT ADMIT OF AN EASY AND PERFECT REMEDY. I AM PERFECTLY SATISFIED WITH IT BECAUSE I DID NOT LOOK FOR PERFECTION IN THIS FIRST MACHINE. THE DIFFICULTY IN THIS MACHINE IS THAT THE CAMS ARE NOT LARGE ENOUGH. THIS, OF COURSE, CAN BE AVOIDED. I THINK MR. KELLAR TOLD WHEN I LAST SAW HIM THAT IF I WOULD WRITE TO HIM INFORMING HIM WHEN I SHOULD BE IN WASHINGTON HE MIGHT BE ABLE TO MAKE SOME SUGGESTIONS ABOUT A HOME DURING MY STAY IN WASHINGTON. I SHALL WISH TO EXHIBIT THE MACHINE. TO SUCH GENTLEMEN AS MIGHT TAKE INTEREST IN A THING OF THIS KIND. I DO NOT WISH TO MAKE A PUBLIC SHOW OF MYSELF OR MY MACHINE. I WANT TO SHOW IT TO MEN WHO CAN APPRECIATE AND UNDERSTAND MACHINERY. MR. ROCKWELL. OUR REPRESENTATIVE IN CONGRESS. VOLUNTEERED TO GET ME A ROOM & I HAVE WRITTEN TO HIM ON THE SUBJECT. STILL I THOUGHT IN CONSEQUENCE OF YOUR MORE THOROUGH ACQUAINTANCE IN THE CITY THAT YOU MIGHT BE ABLE TO MAKE SOME SUGGESTIONS WHICH MIGHT BE BENEFICIAL TO ME IN EXHIBITING THE MACHINE. I WANT A ROOM LARGE ENOUGH TO RECEIVE SUCH COMPANY AS MAY WISH TO SEE THE MACHINE. I WANT A ROOM WHERE I CAN SAFELY LEAVE IT WHEN I AM ABSENT AND WHERE NO ONE WOULD BE LIABLE TO GO IN AND INJURE IT. EXCUSE THE LIBERTY I HAVE TAKEN, AND BELEVE ME

YOURS, TRULY. CHARLES THURBER.

produced, and in conjunction with these movements the paper or tables upon which the writing is to be made has a horizontal movement for spacing off the letters, and, at the completion of the line, a vertical movement for spacing the lines. The model accompanying the application gave evidence of the perfection of the invention, as it made several letters with precision and beauty.*

Inkstands.—A variety of inkstands have been patented during the year, and several ingenious, useful, and ornamental kinds of inkstands have come into use, for which we are indebted to foreign countries. The object to be attained in most of them is to protect the ink from evaporation, and at the same time render it easily accessible.

Type casting.—The art of type casting has within a few years past been brought to great perfection; and under a patent granted in the past year, the process has been so expedited as to leave but little to be desired in this branch of art. The inventor states in the preamble of his description that he has endeavored, in the construction of his machine, to imitate as nearly as possible, by mechanical means, the process of type casting as usually performed by hand.

Type setting.—Many attempts have hitherto been made, without success, to print from types arranged upon a cylinder, the failure growing chiefly out of the difficulty of arranging the types with regularity, and retaining them firmly in position. In an invention for this purpose, for which a patent has been granted, the inventor professes to have remedied the above difficulties, and made printing practicable by this desirable method. The types (of uniform size) are of a pyramidal form, to adapt them to their position around the cylinder, and are held firmly together by means of rules or strips of metal fitting into recesses made in the types for this purpose.

Electrotyping types.—A patent has been granted for an improvement in forming types by the electrotype process, which offers some facilities, although it would appear, in view of the rapidity and precision with which type casting is performed, and the recent improvements in stereotype casting, that the electrotyping process cannot compete with them in point of economy.

Anastatic printing.—Among the notable inventions of the last year is one for printing from, or copying, all kinds of printed work, producing perfect fac similies of old works, and multiplying copies indefinitely. Such an invention cannot fail to excite deep and general interest, and even some alarm, when it is announced that an engraved bank note may be copied with perfect fidelity by the anastatic process. Should this be the case, which is somewhat doubtful, there is not so much to be feared in relation to forgeries as may at first sight be anticipated. *Forgeries* will be made in spite of all obstacles, and experience has shown that the amount of crime of this nature does not increase in proportion to facilities afforded by these so basely prostituted discoveries in science. For every advantage borrowed or stolen by the forger from the open hand of science, she holds in her other hand the checks for villainy—the guarantees of public protection.

For written notes and signatures a test paper is offered, with which

* Since the above was written, an entire letter, written by the machine, has been kindly furnished, of which the annexed engraving is a *fac simile.*

neither chemical nor mechanical devices for erasure can tamper. For printed notes, she offers materials which will counteract the attempts to reprint by anastatic or any other process. As such facilities for reproduction and counterfeiting increase, they are met with corresponding increase of vigilance, and the chance of detection is not diminished. The extraordinary art of anastatic printing has been patented in this country to foreigners, and, as far as ascertained, has been practised with success in the city of London. The patent was granted for the process as hereafter given, and not, of course, for the result or principle. The credit of the discovery, and of the first successful production of copies from an engraving or other printed work, belongs to one of our own countrymen, Mr. Joseph Dixon, now of Mystic, Connecticut; and, according to the most creditable testimony, his results are far more perfect than any hitherto attained by others.* Mr. Dixon has been for many years engaged in perfecting his art, and I can testify from personal knowledge of his success in this invention many years ago. But, as the office was not in possession of the details of his process, no reference could be made to him, and the patent was accordingly granted as above stated. It is possible that the two inventors have aimed at similar results by entirely different means; but be that as it may, it is but justice to a real inventor, and the well-earned reputation of our country in the promotion of the useful arts, that this mention should be made, and credit given where credit is so evidently due. The process of anastatic printing is substantially as given in the following description, viz: "We lay the written or printed side on a clean piece of blotting paper, and wet the upper side equally by means of a soft brush, with a mixture of one part of nitric acid of 1.362 specific gravity, and eight parts of water by weight. So soon as the water has completely soaked through the 'orignal,' we lay it between sheets of blotting paper, and remove the excess of dilute acid by gentle pressure, and if the acid has equally penetrated the 'original,' we lay its written surface on the cleaned metallic surface, place double blotting paper over it, and pass it under considerable rolling pressure, which causes the acid to attack the metal where unprotected by the writing, drawing, or printing, &c., on the original, and produce what we call a negative etching.

"Printed books of ten years generally require about 24 hours, and those of thirty to forty years, some days; but, after that age, no material difference appears to have taken place in the chemical condition of the printing ink. When we consider that the originals have been sufficiently acted on by the acid, we remove the cover and add water, so as to reduce the strength of the acid contained in each sheet to such a degree as that it shall not act strongly or disagreeably on the tongue when brought into contact. We now lay the original between sheets of clean blotting paper, and subject them to slight pressure to remove superfluous moisture; we then lay it on the polished metallic surface as before described, and subject it to much greater rolling pressure than recent originals. If saving of time is an object, and when the originals have been very much indurated and dried, as in engravings, &c., we proceed by washing over the back of the original to be transferred with a solution of caustic potash,

* Mr. Dixon's discovery is mentioned in a work entitled "Science applied to Domestic and Mechanic Arts," by Rev. Alonzo Potter, published in 1841; and in the same work is given a specimen of Mr. Dixon's printing. This work was brought to notice after the completion of this report.

impure rain water, or distilled water, of about 1.014 specific gravity, which we prefer to carbonate of potash, as that substance would evolve gas in the next process; and when the original is fully soaked, we prepare a saturated solution of tartaric acid in water, in a shallow flat basin, or on a sheet of glass with a wax border to form tank sides; we then place the original, which has been soaked in caustic potash, in this solution, with the face to be transferred uppermost, and a reaction takes place between the tartaric acid and potash in the paper, forming crystals of cream of tartar, which appear over the whole surface, and are sparingly soluble in water, leaving only those parts which are protected with printing ink uncovered with crystals. We next roll a hard lithographic inking-roller, charged with a small portion of ink, over its wet surface several times, and in several directions, until the black lines become revived by a new coat of ink, leaving the blank part of the paper covered with crystals almost untouched. We next remove the superfluous ink by a second application of a hard roller, uncharged with ink, and dissolve the crystals of cream of tartar by immersing the paper for some hours in dilute nitric acid, twenty parts water by one part acid of 1.362 specific gravity by weight; after which it is partially dried in blotting paper placed on the metallic surface, 'and subjected to slight pressure as before.'

"We remove the 'originals' from the plate after pressure, and wash the plate over in all directions with very thick gum-water, by means of a sponge, and next rub up or fill in the plate with a linen rag or sponge charged with a mixture of lithographic printing ink and gum-water, wherever it has been protected from the action of the acids, which operation of charging the plate constantly follows the continuous washing with gum, as it is usual for lithographic printers to charge their stones; and if the transfer has been not quite complete, or is from old work, this process should be repeated at intervals of one hour or more."

"What we claim is—

"First, the herein described process whereby we transfer by means of treating the 'originals' with acids of strength varying with the induration of the ink, and so pressing out the acid as to cause an etching of the blank spaces, and a reversed impression of the original (where protected from the action of the acid) or metallic surfaces.

"Second, the process of reviving the printing ink on originals, by first acting on them with caustic potash, or its carbonate, and tartaric acid, so as to form cream of tartar in the paper, which prevents the adherence of fresh ink in the blank spaces, while the old ink is left in a state to take up an additional quantity from a roller pressed over it.

"Third, the herein described process of preventing the adhesion of printing ink, during the operation of printing, to any part of the plates, which are required to remain blank, by acting upon such blank surfaces with acid preparations of phosphorus."

Test paper for notes, &c.—The invention patented under this caption, and before alluded to, consists of a colored or test sheet of paper, covered with a white sheet or surface, or a delicate colored sheet on one or both sides. "The object is to protect the test or colored sheet from being tampered with by any chemical agents employed to obliterate writings, and to prevent the using of any sharp instrument or rubbers for scraping or erasing writings, as, should any chemical agent be employed, the test or colored sheet would be so changed as to alter conspicuously the former appear-

ance of the paper, and the white or delicate sheet or sheets, surface or surfaces, would likewise be imbued with a stain or color produced by the action of those chemical agents on, and thence from the color of, the test sheet; the result, therefore, would destroy the appearance of both, videlicet, the outer white or delicate colored sheet or sheets, surface or surfaces, and the test or colored sheet. This being done, it would be impossible to make the said safety and protective paper assume its original appearance, for, if you attempted to whiten or renew the delicate color of the outer sheet or sheets, surface or surfaces, you would thereby completely destroy the appearance of the test or colored sheet; and, if you attempted to color the test sheet, you would likewise produce a darker color on the white or delicate outer sheet or sheets, surface or surfaces. The one is a protection to the other. As to the application of any sharp instrument or rubber, for scraping or erasing writing, being employed, the effect produced would be such that, when applied sufficiently to obliterate either a figure or word, the test or colored sheet would appear conspicuous, and the part disfigured could not be renovated; consequently the obliteration would always be detected."

"What I claim as my invention is the above described improvement, or manufacture, or combination of a colored sheet of test paper, and one or more plain white, or lighter, or darker, or different colored sheets, or surfaces of paper, applied to one or both sides of the test sheet substantially as above specified."

Printers' ink.—An important improvement has been patented for printers' ink, which consists chiefly in mixing coalaphane, one of the products of the destructive distillation of coal, with the materials known as resins, gum resins, or bitumens, and with lampblack, or black in suitable proportions. The advantages claimed are cheapness, durability, and difficulty of erasion. The ink is freed from empyreumatic odor, and, from the specimens of printing presented, must answer well.

Musical instruments.—Since the grant of a patent, in 1844, for what was denominated the Æolian attachment, or the combination of the piano forte and accordeon, genius has been upon the stretch to improve upon this combination; and the piano forte and accordeon, in their separate uses, have been variously modified and improved. Two patents have been granted for modes of tuning the accordeon reeds. The tuning of the reed is a delicate operation, and is effected by filing off an exceeding small portion at a time, until it vibrates to the proper pitch. By the methods now adopted, the tuning is effected by merely increasing or diminishing the length of the spring by means of sliding rests. In one of the inventions, the claim is made to "tuning reeds by means of moveable clamps, which gripe the reeds and embrace a part of the plate to which the reeds are attached, and admit of sliding or moving to increase or decrease the vibrating part of the reed, and thus regulate the tone."

The claim in the other is, to "confining the thin metallic reeds in a sliding plate, and securing the reed and sliding plate in a case, so that the pitch of the reed may be raised or lowered by the turning of a screw attached to the sliding plate."

Piano fortes.—A patent has been granted for attaching a swell to the piano, for the purpose of giving the crescendo and diminuendo tones, and also, in the language of the inventor, to furnish the explosive tones. The sounding part of the instrument is enclosed in a tight case, provided with

shutters, which, by the action of a pedal, are opened gradually to produce the swell, and suddenly to produce the explosive tones.

In the early part of the year a patent was granted for a mode of producing harmonic tones upon the piano by connecting with a pedal an apparatus which made slight pressure upon the middle of the strings, in imitation of the delicate touch of the finger which produces these exquisite tones upon the violin and other stringed instruments, thus producing the harmonic octaves. Pressure upon other nodal points of the strings would of course produce other harmonic tones.

A patent has also been granted for a mode of striking the octaves upon the piano without the necessity of stretching the fingers after the usual mode. The improvement is to produce, by striking upon one key, the effect that usually results from striking it and the eighth or any particular key beyond it, in order that those persons who find it difficult to reach an octave upon the series of keys may easily produce the same result by striking one single key. The inventors give the following description:

"Our invention is not intended to be limited to the striking of octaves, as it will be evident that a piano forte can be readily arranged so that the effects of any two keys of the series may be similarly produced. In order to illustrate the nature of our invention, we will suppose that the first key hammer of the bass operates upon one, two, or more strings, *a a*, in the usual manner. We will further suppose that the strings *b b* are those belonging to the other extremity of the octave, or that they are sounded by means of the hammer of the eighth key on the right of that first mentioned. In order to accomplish this, it is well known the little finger of one hand must be pressed on one key, and the thumb on the other, the operation requiring a considerable and often very inconvenient stretching of the hand; being, besides, attended with other difficulties and dangers well known to pianists.

"In order to effect the two sounds by means of one key, we arrange by the side of the wire or string *a*, and at a little distance from it, another or supplementary string or wire, which is carried out and sustained over a supplementary bridge, arranged and constructed in such manner as to permit the passage and vibration of the string over it without *contact therewith*, the said bridge having suitable contrivances applied to it for the purpose of sustaining the *supplementary string* at the same level with the strings *a a*.

"This supplementary string *is of the same length, or is tuned so as to emit the same sound*, or as near the same as may be desired, as that of the *strings b b*, or at the other extremity of the octave. The hammer is made wide enough to strike at the same time upon the strings *a a* and the supplementary string, so that when its key is struck, a double sound, corresponding with those of the two extremes of the octave, is produced."

"Having thus set forth our invention, we shall claim one or more supplementary strings, damper, and bridge, (or other analogous contrivance for supporting the strings and checking their vibration as above set forth,) in combination with the string *a*, or strings *a a*, of a note, and struck by the same hammer substantially in the manner above specified. We also claim the making the pad of the hammer-head of different degrees of elasticity, or harder in that part of it strictly beneath, and which rests upon the supplementary string, than it is in the part or parts beneath, and

which strike the other strings, *a a*, the same being for the purpose above explained."

Another improvement of a distinct character, but to attain the same end, has been patented; and although it renders the work of the piano somewhat complicated, yet it must afford much facility in many passages. Any number of keys or hammers are connected together by coupling levers; so that the striking of any one key shall, by means of the coupling lever, strike the note of its octave, and the coupling is so arranged that the parts striking the octaves are thrown out of action at pleasure. The inventor does not intend to limit the application of his invention to the production of octaves, but to adapt it to any other series of notes, as taste may require.

A patent has been granted for a mode of making keyed bugles of tortoise shell. In this ingenious and beautiful device the brilliant tone of the bugle is preserved, while the instrument is made extremely light; and from the elasticity of the material, it is not subject to deterioration of tone from indentations. The instrument is made in five parts, which are welded together in an ingenious and perfect manner.

PHILOSOPHICAL INSTRUMENTS.

Number of applications, 15.—Number of patents granted, 6.

Clocks.—A patent has been granted for an improvement in the propelling power of clocks, by which a regular first mover and maintaining power is obtained without the use of a weight or coiled spring and fusee; which improvement is described as follows:

"I make use of a spring, single or with leaves, fastened by its centre to the bottom of the clock case, or in any convenient place. This spring constitutes the first mover and maintaining power. Now if the cord or chain that is usually wound on the barrel be attached directly to the extremity of this spring, it would draw the said cord or chain with more force, and unwind a greater quantity of it from the barrel at one time than another, so that the movement of the clock would never be regular.

"To correct this irregularity of the spring, I have contrived to have the end of the spring applied to a current lever of the second order, to which the cord or chain is connected, which lever is continually increasing in length and power in the same ratio that the force of the spring decreases or becomes weaker as it extends itself; thus maintaining the action of the spring regularly and equally, which is the great desideratum in the construction of clocks with plain springs, instead of the heretofore used cumbersome and expensive weights."

A patent has been granted for an improvement in the balance wheel of clocks, consisting in the "employment of a suspension piece which sustains the lower sides of the arbor, on which the balance wheel is placed in such manner as to take off the weight of the balance wheel and its arbor from the pivots thereof."

An improvement in the chronometer balance has been the subject of letters patent. The balance is made as usual, of two laminæ of different metals, mounted on the staff by the cross arms in the mode usually adopted; but the rim of the balance is made with the arm so placed relatively with the divisions in the rim, that the spaces between the centres of the arm, from the junction with the rim to the extremities formed by each

division in the rim, is as near as possible an arc, forming a quarter of a circle, instead of being, as heretofore made, nearly or quite an entire half circle.

LEATHER.

Number of applications, 30.—Number of patents granted, 21.

But little of intrinsic novelty or merit has been developed under this head. A patent has been granted for a new mode of preparing skins previous to tanning, with a view to hasten the process; the hide is perforated by very fine steel points, either upon the flesh or grained side, the steel points being very close, so as effectually to pierce the hide, and thus facilitate the introduction of the tanning material. The inventor intends to make this perforation by percussion or pressure. The inventor asserts that the puncturing of the leather does not materially affect its strength, nor make it more permeable to water.

CAOUTCHOUC.

Number of applications, 14.—Number of patents granted, 10.

The rapid progress now making in the art of preparing and applying India rubber, the large number of applications made for patents under this head, have rendered it necessary, in the apportionment of subjects for examination, to constitute a distinct class, under the head of caoutchouc.

Some improvement has been made in divesting the rubber fabric of sulphur, but most of the articles exposed for sale have still a strong odor of sulphur, which is extremely tenacious, adhering for a long time to the fingers, after even a slight handling; and, where the articles are worn, the sulphur escaping tarnishes every article of silver carried about the person. The shirred or corrugated India rubber fabrics, of which suspenders are now so extensively made, is an article of much importance, and has been applied to a great variety of useful purposes. In the report of last year a brief description was given of the shirring process. A patent has been granted for an improvement in the shirring process, which will be best understood from the description of the inventor. Shirred or corrugated India rubber fabrics, which consist of strips or threads of India rubber laid between two pieces of cloth of any kind, have been heretofore made by passing the threads or strips of India rubber, in a stretched state and between two pieces of cloth, (which have the surfaces which come together, and embrace the strips of India rubber, prepared with India rubber cement,) between two rollers covered with some elastic substance, to give the requisite pressure, and cause the prepared surfaces of the pieces of cloth to adhere to the strips or threads of India rubber and to each other.

"This mode of operation, although a great and valuable improvement in the arts, makes an imperfect fabric, with the edges of the ribs formed by the strips or threads of India rubber of an irregular form and rugged, and with the surfaces of the two pieces of cloth imperfectly connected between the strips of India rubber. But my improvements remedy these defects; and they consist, first, in making the rollers between which the fabric is formed of metal or other hard substance, with their surfaces grooved in the direction of their periphery, to correspond with the number and size of the India rubber strips and the spaces between them, the strips

passing in the grooves, and the two pieces of cloth being pressed together between them by the ridges, and the grooves being of such depth as to insure sufficient pressure to cause the pieces of cloth to adhere to the strips of India rubber."

"What I claim as my invention, and desire to secure by letters patent, is the method of uniting the various parts in making shirred or corrugated India rubber fabrics, by passing the cloth and strips of India rubber between pressure rollers, one or both of which is grooved to receive the strips of India rubber, and make pressure on the cloth between the strips.

"And I also claim connecting the driving feed roller with the gearing which drives it, by means of a ratchet, to admit of turning it back to stretch the strips of India rubber, when this is combined with pressure rollers, the peripheries of which move with greater velocity than that of the feed rollers."

Cutting India rubber into threads or strips.—This operation, which is one of the most important preparatory to the operation of shirring, has been usually performed by cutting a long sheet of prepared rubber into narrow strips, by means of a series of revolving parallel knives. The cutting cannot be made in a suitable manner unless the knives are constantly wetted by the dripping of water. A patent has been granted for a new mode of cutting by means of a series or gang of knives, having a rapid or vibratory movement, and carried over the sheet of rubber, which is passed over a smooth roller of metal or of wood, the knives being kept continually wet with the dripping of water.

Another improvement in the cutting machines has been patented, presenting a novel feature. In the usual mode of cutting, the knives, which are of thin circular plates, are arranged upon a shaft parallel to each other, having a plate of metal of the desired thickness between them to keep them the proper distance apart, and the whole are tightly screwed up together by a nut at one end.

An important improvement has been made in the machine for cutting India rubber into threads, and secured by letters patent. The cutting knives have usually been screwed up tightly upon the shaft, and their cutting edges thin and sharp. In the improvement mentioned there are two sets of disks, with their edges of the thickness of the strips of India rubber to be cut, and these two sets, revolving in opposite directions, perform the cutting. A peculiarity of this invention consists in not having nuts or disks between the knives to regulate their distances, the disks or knives themselves performing that function; and thus, as the cutting edges of the knives wear away, they accommodate themselves to the proper distances.

Several patents have also been granted for inventions for new fabrics of India rubber. One consists in impregnating the India rubber, or body of the cloth, with emery, sand, or other suitable grit, or with filings of iron, or other metals, or with other hard substances, thereby making a cloth or fabric firm and solid, and suitable for sheathing vessels, for the covering of floors as carpeting, for the soles of shoes, and a variety of other uses.

Another is for imparting additional strength, solidity, and durability to India rubber fabrics, by combining with it the shearings, clippings, or nappings of wool, cotton, silk, hair, fur, or any fibrous substance. The fabrics made in this way are firm, solid, having a smooth surface resembling leather.

Another patent has been granted for combining stocking knit fabric with sheets of India rubber, the rubber being cemented either between two layers of the knit fabric, or in any other way as to form an elastic fabric. There are many other applications of the rubber fabrics, such as to boats, life preservers, &c., which being special in their character, will be considered under their respective classes. Some very beautiful fabrics have been produced in this country by weaving cotton, silk, or other fibrous materials, with threads of India rubber under tension. It is believed that this invention has been really made in this country, by an individual who had no knowledge of what had been done before him, although it had been patented in England several years before.

CHEMISTRY.

Number of applications, 48.—Number of patents granted, 40.

Salt making.—An important improvement has been received by patent in the manufacture of salt, and, judging from the specimen furnished, and its low price, the inventor or discoverer will not be long in reaping his reward. The claim of the inventor will convey the whole idea in an intelligible manner:

"What I claim as my invention, discovery, art, or improvement, and desire to secure by letters patent, is the art or process of separating the impurities contained in salt water or brine, in its crude state, by adding a sufficient quantity of common salt to the salt water taken from the salt springs, wells, or other source, in its crude state, when properly mixed and dissolved, to bring the brine in the vats or cisterns to immediate saturation, for the express purpose of precipitating the impurities and depositing them in the bottom of the vats or cisterns, without the aid of evaporation or of solar or of artificial heat. I do not claim adding salt to salt water for the purpose of concentration, as is frequently done. But I do claim the process above described of separating the impurities from salt water by the addition of salt thereto, allowing the impurities sufficient time to settle, and the drawing off for evaporation."

Filters and refrigerators.—An improvement in this useful combination has been patented, in which the filter is so combined with the refrigerator that the water, when drawn off from the refrigerator, shall be supplied from the filter, and consume no more ice than is required to cool the quantity of water needed for use. The parts are so arranged that the filtering is upwards, and the direction of the water through the filter may be reversed at pleasure, and thus thoroughly cleanse the filtering materials.

A new plan for a refrigerator has been patented, and differs from most refrigerators for keeping meat, &c., in two particulars, viz: the air in the cold apartment is dry, not being in contact with the ice, and the apartment is ventilated by several modes. Usually, in refrigerators, meat and other articles to be preserved become impregnated with mustiness or unpleasant odors, owing to the moisture from the ice and the closeness of the apartment. The ice is placed in an apartment by itself, through which passes a coiled tube communicating with the external air and the apartment in which the provisions are kept. By means of a fan, bellows, or other contrivance for circulating air, the air is driven through the coiled tube, becoming cooled in its passage, and enters the apartment for provisions in a dry state.

A new oil, which the inventors have denominated the *American oil*, has been patented, and from the specimen afforded it must answer the purpose of lubrication in place of the fatty oils. It is obtained by the dry distillation of resin. Oil of a certain character has been before obtained from the destructive distillation of resin, but the inventors claim that they have discovered a new hydro-carbon, not before known to chemists. This interesting class of compounds is frequently receiving new contributions, and as slight changes in the processes, even of temperature, result in new combinations of hydrogen and carbon, the presumption is in favor of the discovery.

Coloring matter from quercitron.—The patentees of this process have, by a slight modification of the process of separating yellow coloring matter from quercitron bark, introduced a substantial improvement. When gelatine is added to a decoction of the bark, the tannin combining with the gelatine leaves the coloring matter precipitated and partly suspended in the liquid. The coloring matter thus separated is impure and deficient in brilliancy. In the improved process the decoction is made and brought to a certain degree of concentration, and allowed to stand for a sufficient time for the coloring matter to subside, when the supernatant liquid is drawn off and the coloring obtained in a clear and bright form. The process has a twofold bearing. The liquid drawn off is used for tanning, and the coloring is fully extracted and of a superior quality.

Coloring matter from spent madder.—A very considerable saving is effected by an invention for obtaining a good available coloring from spent madder. To three pounds of washed spent madder, five gallons of water are added, impregnated with sulphuric acid, so as to raise its strength one degree by the hydrometer. After standing two minutes, the water is drawn off, and five gallons more of water added, with eight ounces of soda dissolved in warm water, for the purpose of neutralizing any remaining acid. In this state it is allowed to stand fifteen minutes. The liquor is then filtered off, and the residue dried in a warm and close room; and when pulverized, it is ready for use as madder is ordinarily used. From the specimens presented to the office, no doubt can be entertained of its value, if the result is certain in all cases, for it makes from that which is ordinarily thrown away an available article.

Concentrated portable jelly.—Letters patent have been secured for a mode of preparing gelatine in such manner that a small portion of it added to hot water, and turned into moulds to cool, affords at once a palatable jelly, with no other labor of preparation. The jelly is brought into a concentrated state by evaporation in vacuo, having previously all the condiments necessary for flavoring mixed with it; it is then packed in bottles and is ready for use; the whole making of the jelly being simply the dissolving a small portion of the concentrated jelly in hot water, and suffering the whole to cool.

Rotting hemp.—This subject has suddenly become one of much speculation and contention among inventors, and it appears that some important improvements have been developed in the preparation of hemp and flax, particularly in the rotting process. In the old process of water rotting, the time required varied from five to fourteen days according to circumstances; in the process of dew rotting, from two to six or eight weeks; and in the process called mixed rotting—that is, commencing the rotting in water and completing in the air—from two to three weeks. Under the recent im-

proved processes, the whole process is completed in a day and a half, or two days at farthest. In the old methods the natural temperature of the air or water was relied upon, and of course the process was more or less rapid as the temperature was higher or lower. In the new mode artificial heat is resorted to. The hemp or flax is put into large vats and steeped in warm water, until it is completely macerated; and as soon as it is brought to this macerated condition, the temperature is suddenly raised to the boiling point, which arrests all further rotting. The critical point in hemp rotting is to check the putrefactive process at the proper time, and where it depends upon the fluctuating temperature of the air, it requires the greatest care and discernment to ascertain when the operation must be checked.

A patent has also been granted for some improvements in the modes of watering, handling, and otherwise managing the hemp.

Hydro-oxygen blowpipe.—An important improvement in the compound blowpipe has been patented, the inventor and patentee being well known in our country as the original inventor of this valuable gift to science and the arts. As the specification of claims by the inventor is somewhat descriptive of the character of the invention, and will be given in your report, the details will not be necessary in this place. By the aid of the recent improvements the metallurgist and artisan are furnished with the means of fusing large quantities of platinum and other refractory substances which refuse to yield to the heat of the most powerful furnaces.

Composition for the bearings of machinery, &c.—Several inventions in years past have been patented for this application, and have been found to answer a good purpose; but the one before us possesses extraordinary merit as to cheapness and durability. A trial has been made of a box for railroad cars, which, after running forty thousand miles, exhibited no perceptible marks of wear or friction. The attention of the government has already been directed to this invention.

Sugar making.—Some valuable improvements have been secured in this extensive business tending to economize fuel in the process of evaporation. In one of them, the evaporating pans, instead of being heated by steam at a distance from the generator, are set directly into the top of the boiler, thus saving much in the construction, and preventing the waste of heat from condensation of the steam. In combination, also, with this device, the boiler is divided into two parts by a partition, in which is placed a controlling valve, by which the temperature can be raised and regulated, as may be required for different stages of the operation.

A patent has been granted to a foreigner, whose name has been favorably known for many years as one of the most successful promoters of the art of sugar making, and is identified with the introduction of one of the most valuable improvements ever made in this connexion, viz: the clarification of sirups and sugars by animal charcoal, and also the restoration of the animal charcoal after it has become *effete*, as it is termed. His present patent is for an improved process of restoring the charcoal, and also for a method of evaporating and condensing by the same apparatus. A series of tubes, conveying steam, are so arranged as to receive the percolating sirup upon their exterior surfaces; and these tubes are connected with the vacuum pans, so that the condensation effected by the evaporation of the sirup is employed to keep up the requisite degree of rarefaction in the vacuum pans.

The past, as well as many former years, has not been without proofs of the inventive powers of the fairer sex. A patent has been granted to a lady for an ingenious device entitled the *submarine telescope*. The instrument has been put to practical tests, and by its aid the exploration of the bottom of a deep river was made in the most satisfactory manner. The instrument is adapted to a variety of purposes, and will not only be useful for many operations of a directly practical nature, but will be of much interest and value to the man of science and naturalist, in acquainting him with the character, mode of growth, &c., of submarine plants, and a thousand other objects now hidden from his vision.

In reviewing the inventions of the past year, the proverbial genius of our countrymen appears to have fully sustained its title, and, did time allow of the comparative estimate, would be clearly shown to have transcended the efforts of other nations, where science can boast of extensive patronage, and real genius rarely escapes the encouragement of wealth. A single allusion may serve to illustrate.. Morse's *electro magnetic telegraph*, one of the most interesting and important inventions of the present day, has, during the past year, been established by the most conclusive practical tests, and, also, by the admission of foreign powers, to be superior in point of economy, facility of transmitting intelligence, and simplicity of construction, to all other known telegraphs. In conclusion, I may remark, that many patents of value, both to the inventors and the public, may have been unnoticed in this brief report, for the want of time, and specially for the reason that the intrinsic worth of inventions and their successful application are not often considered or investigated—the business of examination being chiefly confined to the questions of novelty and patentability. I have therefore endeavored to confine my attention to such of the number as would afford a general idea of the progress made in the several branches of art and science, and of the development of new principles in science and their applications to the arts.

Respectfully submitted.

CHAS. G. PAGE,
Examiner of Patents.

Hon. Edmund Burke,
Commissioner of Patents.

H.

Report of W. P. N. Fitzgerald.

Sir: In compliance with your directions, I submit the following report upon the progress of inventions during the last year, so far as they have come under my observation in the classes committed to my charge. I should follow the example of my predecessor, and extend my report to important inventions made in foreign countries, but my duties have been so heavy and pressing during the year that it has been impossible to give any considerable attention to foreign journals beyond what was requisite in the examination of cases upon which I was called to act.

In the first report made by my predecessor, a historical sketch was given of the progress of the arts from their infancy to the high degree of maturity and perfection which then characterized them; together with a concentrated but comprehensive view of their then present condition throughout the world. This report emanated from one of the master minds in the arts, and it would be a work of supererogation to reoccupy the field so ably explored by him. A glance at that report, and the one which succeeded it, will satisfy you that it is unnecessary for me to extend my remarks to inventions made prior to the commencement of the year which has just terminated.

The classes subject to my examination are—

1st. Metallurgy, and the manufacture of metals.

2d. Manufacture of fibrous and textile fabrics, and all machinery therefor.

3d. Engines operated by steam or other gases.

4th. Navigation, and marine implements.

5th. Civil engineering and architecture.

6th. Land conveyance, including all kinds of vehicles for travel or for transportation.

7th. Mills of all kinds for grinding grain, &c.

8th. Machinery for working lumber.

9th. Fire arms and implements of war.

10th. Miscellaneous.

11th. Hydraulics and pneumatics. This last mentioned class was transferred to me in September, 1845, having previously been examined by my colleague.

Each of the above classes includes a great variety of subjects, differing widely from each other, and requiring numerous subdivisions, which I shall review in their proper order.

Before entering upon this duty, however, justice to inventors and to myself requires me to say, that many important inventions, for which patents have been sought during the past year, will necessarily be overlooked, from the fact that, although more examinations have been made than at any other equal period in the history of this office, there are still nearly one hundred applications in my desk upon which I have not been able to bestow a passing glance.

And although there may be inventions among them which will mark eras in the progress of those branches of the arts to which they belong, they must, for the present, be passed over in silence, and made the subject of a future report.

METALLURGY AND THE MANUFACTURE OF METALS.

But little has been developed during the past year, before this office, connected with the art of separating the metals from those impurities with which they are mingled or combined in the mine.

Gold.—This metal, which is found merely *mixed* with impurities, may be separated by means wholly mechanical, the heat and chemical agents necessary in purifying the baser metals neither being necessary nor applicable. The improved process of washing, noticed in the last report of my predecessor, is the last improvement which has come under my observation, whose object was to separate gold from its impurities.

The attention of metallurgists is still principally directed to the manufacture of iron, which, from its vast and increasing importance, and the numerous practical difficulties attendant upon its manufacture, still presents many problems for the scientific and practical iron-master to solve. The substances with which iron is combined in the various kinds of ore—those used for effecting their decomposition and separation—their proportions and affinities, are, in general, ascertained with comparative ease; but the intensity of the heat, the regulation of the quantity of decomposing matter, the mode of exposing the ores, the manner of directing the current of burning gases, or other ignited matter, upon the mass, the form of the furnace, &c., require such nicety of practical adjustment and adaptation, and are so easily deranged, that the best process which science could suggest might, in consequence of a slight practical defect, prove utterly unsuccessful. The ease with which the iron combines with the materials used in decomposing the ores also presents a serious obstacle in the way of obtaining it in its purity. The substitution of one material for another in the process, which is composed of similar elements, will frequently produce very important changes in the result; and it would be extremely difficult for the mineralogist and chemist in many cases to give a sound reason for the failure of the one process while the other is crowned with success. Patents, therefore, for apparently very inconsiderable changes in the process or materials used in reducing ores, when there are improvements in results, should be readily granted.

Patents have been granted within a few years, both in this country and in Europe, for modes of obtaining pure malleable iron directly from the ores. It is doubtless true that experiments of this kind have sometimes been attended with success; and at other times, following apparently the same process, they have failed. The processes heretofore patented, although they may possess great merit, do not appear to have been characterized by that uniformity of result which is so essential in any branch of manufactures, and which alone commands public confidence and patronage. They have not all of them, however, been fully tried, and perhaps will yet produce, under skilful management, practical results of a highly satisfactory character. One patent for an invention of this kind has been granted, in this country, to a foreigner within the last year, and the process is as follows, in his own language:

"By my process, I am enabled, in a very short space of time, to manufacture wrought or malleable iron from the richer kinds of ore, such as the hematitic, and others, which contain not less than forty-five *per cent.* of metal, and which generally contain a considerably larger quantity; my

process not being considered as adapted to the earthy ores, or to any of those which contain a less per centage of iron.

"Before proceeding to give the particulars of my process, I will remark that the invention herein described is the result of a series of experiments, by which I have ascertained that the attempts heretofore made for converting the richer iron ores into malleable iron, by means of carbonaceous matters in reverberatory furnaces, have failed principally from a want of knowledge of the effect of carbonaceous substances, when so employed, as regards quantity; the proportion added to the ore having been much too small to answer any good purpose, as it was not capable of de-oxydizing any considerable portion of the ore, and the means attempted were not such as would particularly prevent such small quantities from being again oxydized by the working of the reverberatory furnace. Although I do not claim, therefore, to be the first who has made the attempt to manufacture malleable iron from the ore in a reverberatory furnace, I do claim to be the first to have discovered the cause of former failures, and to have devised the means of rendering the process successful.

"In reducing the kinds of ore referred to, which consist principally of the protoxides and peroxides of iron, I have discovered that not less than from twenty to forty per cent. of carbon, by weight, and in many cases more, should be mixed with the ore when it is to be reduced in a reverberatory furnace; and I exclude from the list of those which are to be so treated all such as do not contain a sufficient quantity of oxygen to require the lesser proportional quantity of carbon above named. It will be seen, therefore, that my process applies to that class of ores which, under the ordinary mode of treatment, are deemed refractory, these being the most available when subjected to the process invented by me. With the several ores that I employ, the actual quantity of carbon, or of carbonaceous matter required, will vary considerably, although it will always be equal in amount to that above stated; and I will hereinafter give such information as will enable the workman to judge readily when he is using the proper relative quantity for the iron ore upon which he is operating.

"I commence my process by taking any of the rich iron ores, including under this denomination those only which will yield forty-five per cent. and upwards of that metal, either as they are obtained from the mine, or as they exist after the carbonic acid, or other volatile matter which they may contain, has been separated from them by being calcined or roasted, and which, when so operated upon, will contain that per centage or more of iron by analysis. By means of millstones, rollers, or any other suitable apparatus, I crush or pulverize the ore, which I am about to reduce into particles, sufficiently small to pass through a riddle or screen, the meshes of which measure from one-fourth to one-eighth of an inch, preferring the smaller size. To one hundred parts of the ore, or calcined iron stone, so reduced in size, I add from twenty to forty parts, and frequently more, of carbonaceous matter, such as coke, charcoal, peat, or anthracite, which has been in like manner reduced to powder and passed through a sieve, or screen, of the smaller size mentioned; and, after well mixing them together, I pass a charge thereof, usually of about five hundred pounds weight, into a puddling or reverberatory furnace, which may be of the ordinary construction, and heated in such manner as to be in a state suitable for receiving pig iron to be puddled. This mixture should be occasionally but moderately stirred up—say every five or ten minutes; and,

after some time, dependant upon the heat of the furnace, as well as upon the particular ore under treatment, it will become pasty under ordinary circumstances; this takes place in about half an hour, the pastiness resulting from the hotter parts having become metallic, and adhering or welding together; the furnace is then to be brought to its greatest heat, and the charge balled; but the iron must be previously kept as "*open*" as possible, and care must be taken that it be not balled up too soon, otherwise it will be tender, and most probably *red short*. In about an hour and a half or two hours from the time of charging, if the furnace be properly constructed, the fuel good, and well managed, the charge will be ready for the hammer, and may be treated as puddled iron made on the customary plan.

"It will be obvious, from the remarks already made, that the definite quantity of charcoal or other carbonaceous matter cannot be prescribed, without taking into account the exact quantity of oxygen contained in the ore or calcined iron stone, and of the quantity of carbon, or of carburretted hydrogen, supplied by the carbonaceous matter employed; but, from my experience, I would recommend, as an approximate rule, that where a hundred parts of the ore under treatment contain about fifty of metallic iron, about thirty parts of charcoal, or its equivalent in other carbonaceous matter, be added thereto, and for every additional two parts of iron in one hundred of the ore I would add one part of carbonaceous matter.

"I have sometimes combined with my process of reducing the ores of iron in the puddling furnace the additional operation of bringing pig plate, or other cast iron, into the state of malleable or wrought iron, by adding portions of such cast iron to the mass which is being acted upon. This pig or cast iron, which is a carburet of that metal, not only assists in the reduction of the oxide of iron still remaining in the ore, but has its own carbon separated by the oxygen of the ore. I prefer to add the cast iron when the charge of ore begins to feel heavy or pasty.

"When the cast iron is thoroughly melted, and well incorporated with the ore, the action of each material on the other so rapidly quickens the process, that some difficulty is experienced in preventing its being balled too soon; but, as before stated, the mass should be kept "*open*" at a high degree of heat. Thus not only does the addition of cast iron increase the production of malleable metal, with a given cost of time and and labor, but it also, from causes scientifically accounted for, operates as a desirable adjunct in facilitating the process.

"I do not name the relative proportions of ore and of cast iron, nor do I limit myself to the time of adding them together, as these conditions may be varied at the will and according to the experience of the operator; but it is best to use a smaller proportion of cast iron when a very pure ore is being acted upon, or the quality of the wrought iron may be injured in some slight degree.

"The workman will, after a little experience, be able to determine whether the requisite proportionate quantity of carbonaceous matter has been added to the particular species of ore under treatment, by paying attention to the following particulars:

"First, if, in the working of a particular description of ore, the return of iron be deficient in yield with reference to its known contents by analysis—say less than from two-thirds to three-fourths thereof—and that a larger proportion of slag or cinder runs from it than might be expected,

and if all appearance of the presence of carbonaceous matter vanishes at at an early stage of the process, there is manifestly a deficiency of carbon, and it must be increased in working the subsequent charges.

"Secondly, if the return be good, but the metal does not ball up readily, or stand the hammer well, and if a considerable portion of the carbonaceous matter be seen floating on the molten cinder at the close of the operation, there is too much carbon in the mixture, and in future charges its quantity must be reduced.

"Thirdly, if the cinder be moderate in quantity, if the iron ball up readily, if the carbonaceous matter disappear about thé time of balling up, and the bloom stand the hammer well, the proportions may then be deemed correct."

This process has also been patented in England. Its usefulness can be determined by experience only. It is useless to theorize upon it.

It is confidently asserted that one of our own countrymen has invented an apparatus and process by which the pure malleable metal is obtained directly from the ore, in a perfectly satisfactory manner, and with uniform results, and that the invention has been fully tested. If such be the case, I shall be able in my next report to give you a full account of the invention and its practical operation; but, at present, it would, for many reasons, be premature.

Some of the most important improvements which have been made within the last few years in the manufacture of iron are, the introduction of the hot-air blast, the saving of the combustible gases, which had formerly escaped through the chimney, returning them for use, and in changing the fuel, prior to use, into combustible gases, which are afterwards used in an ignited state with atmospheric air, to produce the heat required for the operation. The general principles having been promulgated, and their efficacy fully established by experience, inventors have since been occupied in discovering new modes and varieties of application. Within the last year, letters patent have been granted for a mode of applying the hot blast to bloomeries, which appears to be of sufficient importance to insert. The following is the language of the inventor:

"In the manner of arranging the pipes for obtaining the hot blast, as herein represented and described, I do not claim that there is anything new or of my invention, I having in this particular adopted a system of pipes for heating the air first used in England, and known under the name of Nelson's pipes for the hot blast. My improvement consists simply in the manner in which I have combined these pipes with the bloomery forge-fire or chimney. I am fully aware that there is not any novelty in the mere application of the hot blast to the bloomery forge, this having been carried into operation in a great variety of ways; but I have, as I verily believe, so combined the hot-blast pipes with said forge-fire, as to obviate the several objections which have, in practice, been found to interfere with those erected prior to my carrying my plan into operation. In most instances the air has been heated in an arch erected at the tunnel-head of a furnace, within which head-pipes have been arranged in a manner substantially the same with that herein described; but in this case, as well as under some other arrangements, besides the necessity of erecting an expensive arch of fire-brick, the plan itself has not answered the purpose intended; the particles of ore and of cinder which have been prevented from escaping have been found to fill up the openings in the arch,

to obstruct the draught, and to adhere to the pipes in such quantity as in a short time to prevent the air that passes through them from being duly heated, in a few days' use only, as I have repeatedly experienced; they are thus rendered incapable of heating the air to such a degree as to produce any useful effects.

"In my plan, it will be seen that the heating pipes are in close proximity with the bloomery fire, and that I dispense entirely with the arch, while I give to my chimney such a form as to produce all its anticipated benefits, without its cost or inconveniences.

"Having thus fully described the nature of my improvement in the manner of applying the hot blast to the bloomery fire-forge, I do hereby declare that I do not make any claim to the applying of the hot blast thereto; nor do I make any claim to the form or combination of the pipes for heating the air, this being the same with numerous others which have been long known and used; but what I do claim as of my invention, and desire to secure by letters patent, is the manner in which I have combined said pipes with the bloomery forge-fire, by placing them within the chimney, immediately over said fire; which chimney is formed in the manner herein described and represented, so as to effect the desired object, without the use of an arch or any analogous structure. To this particular combination and arrangement I limit my claim."

Two patents have been granted within the past year for the generation of the above mentioned combustible gases, and their application to the manufacture of iron. Both are reissues of patents granted and noticed previously, and it is therefore unnecessary to dwell upon them in this place.

No patent has been granted in this country during the last year for improvements in the manufacture of steel.

In concluding my remarks upon this branch of the subject, it is proper to add that the inexhaustible supply and variety of iron ores in this country, and of the materials used in reducing them, and manufacturing the various kinds of iron and steel, and the extensive demand for these indispensable products, render it a matter of the utmost importance to us, as a nation, that the processes connected with this branch of the arts should reach a degree of perfection which they have not hitherto attained in this country; and the ingenuity and enterprise of our manufacturers furnish the best guarantee that we shall not be long in attaining that eminence in this branch of manufactures which appears to be our natural right.

MANUFACTURES OF METALS AFTER THEY ARE SEPARATED FROM THE ORES, AND THE MACHINES USED THEREIN.

Forges.—But little evidence of improvement in the blacksmith forge has come before this office during the past year, but one patent having been granted within that time. Blacksmiths have heretofore found considerable inconvenience to arise from the extinction of their forge fires, in the ordinary course of their work, which is such as to leave the fires unused occasionally for intervals of time. The fire during this time becomes extinct, and time and fuel are consumed in rekindling. To obviate this difficulty, and to render the forge portable, the patentee has provided it with pannels, which slide in grooves in the cover and bottom of the forge,

in such a manner as entirely to surround the fire, leaving a small opening at the bottom for a moderate supply of air to it, and another at the top to perform the ordinary office of a chimney.

Several applications have been made for alleged improvements in tuyeres for conducting the blast to the forge fire; but none of them have presented the requisite novelty to secure letters patent, and are therefore rejected or returned to the applicants for amendment.

One patent was granted early in the last year for improvements in trip-hammers for working large masses of metal; but as I find it described in the last report of my predecessor, it is unnecessary that it should be here described. It is stated by my predecessor, however, that it avoids a practical inconvenience in the steam-hammer, previously patented, to wit: the inconvenience arising from the upsetting of the piston-rod. It is but justice to the first patentee to state that, in making this objection, my predecessor overlooked the fact that the piston-rod was united to the hammer by a spring attachment, to prevent upsetting. The difficulty in practice had, therefore, already been foreseen, and the appropriate remedy applied. If this circumstance had been noticed, the remarks above alluded to would have been withheld, as the gentleman who made them would have been the last to prejudice the rights of an inventor.

Butt-hinges.—Only one patent has been granted during the year for butt-hinge machinery, and that was a reissue of an old patent for making the joints, &c. of wrought iron hinges by the use of appropriate cutters and dies. The patent is too well known to require description. Two patents have been granted for improvements in window-blind hinges.

Pins.—But one patent has been granted within the year for the manufacture of pins, and that to a foreigner. It is proper to remark that the pin machinery of this country is far superior to any other in the world. The machinery patented, however, has its important characteristics, and will be understood by reference to the claims which I give, as follows:

"Having now described the construction of the improved machinery to be employed in the manufacture of nails, rivets, screws, and pins, I desire it to be understood that I claim, in reference to the heading of metal rods or wire for the above purposes, the means of effecting what I call a 'double upset,' viz: by crushing the end of the rod or wire for forming the boss or head of the nail, rivet, screw, or pin, by two or more operations of a single heading-punch and pair or set of holding dies, and the sliding guides, the whole in combination as above described, the rod or wire being brought forward between the holding dies a short distance by the sliding guides, after the first or partial crushing of the metal, to complete and perfect the form of the boss or head, when the second pressure of the punch is brought up against it. As respects the pointing of pins, and discharging them from the machine, I claim my improvement therein—the same consisting in imparting to the sliding-bar (I) certain alternating lateral and back movements in its bearings, as described, whereby the pins are turned in opposite directions during the action of the mill-roller upon them, and discharged from the machine when the pointing of them has been completed."

File-cutting.—This operation has in general been performed by hand, when the best article was required. As it is almost impossible to find a blank of the same degree of hardness throughout, the blow upon the chisel should vary in force, not only according to the *width* of the blank

to be cut, but also according to its varying hardness. Both of these requisites can easily be attended to by a skilful operative; but as these varieties of hardness occur irregularly, no machine has yet been invented which can perfectly adapt itself to them.

One file-cutting machine has been patented within the last year, in which the file blank is placed upon a carriage under the chisel, so that the edge of the chisel shall make the desired angle with the blank, the parts being adjustable in this particular. The hammer which operates upon the chisel works like an ordinary adjustable tilt-hammer. The force of the blow is regulated by a spring, the power of which is again regulated by the width of that part of the file upon which the chisel is operating; and thus, if the blank be of nearly equal hardness throughout, as it moves onward by the regulated intermittent motion of the carriage, it will be properly cut.

Spikes, nails, and rivets.—But two machines of this class have been patented during the year. Very excellent machines have been in use for several years, and secured by patents, and very little progress has since been made. The more recent machines may operate well, but exert no important influence upon this branch of manufactures.

Wood screws.—Two screw machines have been patented, and, although improvements, they operate upon the same general principles with some of those which were previously in use.

Locks and fastenings.—Some ten patents have been granted for machines belonging to this class during the year, and, although several of them are useful, no one seems to possess that distinctive character or commanding importance which entitles it to notice above the rest. They are all modifications of locks, latches, &c., previously in use.

Lead pipe.—For several years past valuable machines have been in use in this country, and a vast amount of pipe has been manufactured. The machines in use give satisfaction, and the improvements made in this branch of manufactures have reference to minor details, while the general characteristics of the machine are preserved. Two patents have been granted the past year for such improvements. In one of the machines patented the cylinder from which the lead is forced through the matrix or former is substantially a double-acting force pump, and is connected with an air chamber for the purpose of preserving a regular stream. This cylinder is located partly within the heater and partly within the furnace. By this construction the operation of forming the pipe can be continued any length of time—the cold lead being regularly supplied to the heater, and one end of the cylinder being filled by suction, (pressure,) while the lead is forced from the other into the air chamber, and thence continuously through the apparatus for forming and cooling the pipe. The other patent is for tinning the interior of the pipe, which is effected by forcing the melted tin, during the formation of the pipe, into a tube in the core, and thence discharging it, through numerous small openings on all sides of the mandril, upon the interior of the pipe.

Tools.—Several inventions of machines under this title have been patented during the year: such as the blacksmith's vice, hammers, augers, saw-filers, drills, &c.; but there is but one which it is necessary to describe. Letters patent have been granted within the year for a machine for boring the cylinders of rotary steam engines, and for other similar purposes, which deserves notice. The operative part of the machine is at-

tached to the end of an arm, which is attached to, and revolves with, a shaft, which is placed in the position which the shaft of the rotary engine is intended to occupy. The cutter is attached to a small shaft which revolves in the outer end of this arm, and is perpendicular to the arm and to the main shaft. It will readily be perceived, that with this arrangement, when the cutter is properly set and the solid ring of metal is placed around the main shaft and properly adjusted, the revolution of the main shaft—the ring being immovable—will cause the cutter to cut a slight groove in the rim. The shaft of the cutter is then geared by cog-wheels, &c., to an immovable cog-wheel, surrounding the main shaft in such a manner that the cutter shaft will revolve very slowly as the main shaft revolves, and thus the width of the groove at first cut is increased by degrees until the boring is completed. It will be evident that the groove bored in this manner will every where, when cut by a plane passing through the axis of the main shaft, present a portion of a perfect circle of an uniform radius.

Other patents have been granted within the year for inventions more or less meritorious belonging to the class of metallurgy and the manufactures of metals, but to notice them all particularly would be to extend this part of my report beyond its appropriate limits.

MANUFACTURE OF FIBROUS AND TEXTILE FABRICS.

This class, for the variety and complexity of machinery which it presents, is perhaps unequalled by any other; and although it has exercised the powers of the most inventive minds for ages, and comprehends machinery producing results which are almost incredible, still every year furnishes valuable contributions to its already munificent stores. It is not to be supposed that every branch of this comprehensive class has equally advanced; but while some have remained nearly stationary, others have made steady progress. The subdivisions of this class will appear as I proceed to notice them.

Preparation of fibres.—Cleaning and carding wool.—There have been but three or four patents granted within the last year in this division; one for carding, and the others for cleaning and burring. Although the machines patented possess novelty and merit, they do not so materially differ from machinery previously used as to render a particular description of them necessary. No patent has been issued for wool combing.

Cotton gins.—Several patents have been granted for cleaning cotton, and one for ginning the long staples. This cotton gin is an improvement upon that variety which is known as the "roller gin." So far as I am acquainted with the machines heretofore in use for that purpose, they have produced to some extent an injurious influence upon the cotton, in consequence of the pressure, rubbing, and strain upon the fibres, made by the rollers; the cotton thus becomes "dead," as it is termed, and can be easily distinguished from that which is picked by hand; while the machine patented is said to produce an article *equal* to that picked by hand. The cotton is carried from the hopper, by a toothed cylinder, to a large cylinder with fan beaters or ribs, which is covered by a cylindrical case that opens on the side opposite to the feeder into a funnel-shaped box, whose bottom inclines downwards. The large ribbed cylinder, as it revolves, takes the cotton from the feeder and throws or blows it down to the lower

end of the box, where there is an opening to two grooved ginning rollers, to which the cotton has easy access. These rollers, as they revolve, are prevented from separating by a weighted lever resting upon an adjusting screw. The ends of the rollers are made for a short distance smooth, and of the slightest increase of diameter, which keeps the grooved portion of the rollers separate from each other, but not so far as to prevent their drawing the cotton between them. The pressure of the weighted lever does not come upon the cotton unless the supply is too large, and in that case it operates to regulate the supply. Thus the injury arising from pressure, straining, &c., is avoided. A little above and in front of the upper ginning roller, and a little below and in front of the lower one, there is placed a fluted roller, working very near to the ginning rollers, and in opposite directions, (at the points where they meet,) which strip the ginning rollers of the long fibres which would otherwise wind around them. The operations of this machine are said to be entirely satisfactory; and if so, an important step has been taken in this branch of manufacture.

Preparing the fibres of hemp and flax.—Inventive genius is still industriously exercised upon machinery for separating the fibres of hemp and flax from their woody connexions, and preparing them for manufacture. Many applications have been rejected for want of novelty, and seven or eight machines have been patented. These patents have generally been granted for slight modifications of pre-existing machinery, still operating upon principles well known. One of the patents I will, however, notice, as it seems to present a feature distinguishing it radically from the rest. The breaking of flax or hemp has heretofore been effected by a series of permanent blades, variously arranged, with movable blades arranged in a manner to correspond, and working between them, or by its being carried between fluted rollers, &c., &c. While the hemp is unbroken the stalk is of such a form, and the fibre adheres to the woody part in such a manner, that if the stalk be broken abruptly, without previous preparation, or if rubbed violently by any machinery used in breaking, more or less of the fibres will be broken or injured. The machinery heretofore in use, and above alluded to, has generally been of a character thus to injure the fabric, though the defect in some is vastly less than in others. To remove this imperfection in pre-existing machinery, the patentee above alluded to first receives the hemp, &c., from the feeding apron between two smooth rollers, which flatten it and slightly disengage the fibres from the woody part, and afterwards feed it to a double series of *small smooth* rollers, the upper series working opposite the spaces between the lower ones, the rollers of each series being placed so as nearly to touch each other, and the upper series being pressed down upon the lower by weights, &c. The surfaces of all these rollers move with a speed equal to that of the flattening and feeding rollers, and in the same direction, so that the hemp is carried through these series of rollers, and is successively bent in a short curve upwards and downwards, without the slightest tension, rubbing, or injurious breaking, until the fibres are entirely loosened from the woody part, which can then be shaken or beaten out in any convenient manner. The patentee unites the above described machine with other parts for cleaning, which I do not deem it important to describe.

Some of the other machines patented during the year approximate the same point which seems to have been attained by the inventor whose machine I have described.

Spinning.—Cotton, prior to being spun, is formed into roving, which is sometimes deposited in cans, from which it is withdrawn to receive the necessary additional twist. The ordinary mode of depositing the coils in the can is around its inner sides, leaving a considerable space in the middle, thus limiting the quantity it will contain, and leaving the coils in danger of falling in such a manner as to become entangled with each other and break. To remedy these inconveniences a machine has been invented by a foreigner, for which letters patent have been granted within the year. In this machine the guide for the roving, together with the drawing rollers, revolve upon a shaft which is eccentric to the can to such a degree that as the guide and drawing rollers revolve in one direction, and the can in the opposite direction, with different velocities, the roving is deposited in coils or loops which extend from the centre of the can to the sides in all parts of it. Thus the can is filled, the roving well supported, and in condition to be easily withdrawn without breaking.

Several patents have been granted for improved machinery for spinning. In one of those machines the bobbins of the whole spinning frame are supported by their lower and inner edges, upon the outer edge of a large horizontal wheel, from which they derive their motion.

At high speeds the "live spindle" has been found to vibrate to such a degree as to break the thread so often that it has been necessary to drive it at a speed much less than is desirable. This inconvenience was, to a considerable degree, obviated by supporting the spindle in a tube extending up from the traverse rail, which very much diminished its vibrations; still, however, it was found necessary to limit its speed. Letters patent have, within the year, been granted for extending the tube both above and below the traverse rail, by which improvement it is found that the spindle can safely revolve at a much higher speed than before.

Two or three years since, letters patent were granted for supporting the bobbins in the spinning frame by the edge of the belt which gave them their motion. This mode of supporting them is said to be defective, inasmuch as the bobbin frequently flies up from the belt; and, when that is the case, it fails to receive the necessary rotary motion. Letters patent, within this year, have been granted for an improvement intended to remedy this defect. For this purpose the lower end of the bobbin is extended down a little farther than the width of the flat belt which is used. Around this lower part of the bobbin a groove is cut of proper width to receive the belt loosely, and of sufficient depth to prevent pressure upon the bobbin by the belt. This groove receiving the belt, if the bobbin rises or flies up, the lower flange of its groove will touch the belt and receive the proper rotary motion from it.

The foregoing are nearly all the patents connected with the subject of spinning which have been granted during the year.

Weaving.—Nine or ten patents have been granted during the year for improvements in various parts of the loom; but such machinery is generally of a character so complicated that it would be impossible to give an idea of improvements made upon it, without elaborate drawings and descriptions. In one of the looms patented the improvement consists in attaching to the loom a simple apparatus which, in ordinary weaving, will answer as a substitute for the Jacquard. Its merit consists partly in the ease with which it can be attached to hand looms already constructed,

which have no machinery for raising the figure. In many cases it may be very useful.

In weaving by power, where the shuttle is thrown with great force and is arrested by the picker in the opposite box, the steel point of the shuttle sometimes penetrates the picker, and adheres to it in such a manner as seriously to interfere with the movements of the shuttle box. In one of the looms patented this inconvenience is obviated by placing on the picker cam a slight protuberance which shall operate upon the treadle, at the moment the shuttle is at rest, in such a manner as to move the shuttle forward far enough to clear the picker; and before changing the box, the treadle is relieved, and the picker falls into its usual resting place, so that neither shuttle nor picker will interfere with the operations of the box.

In weaving Brussels carpets, and other figured fabrics of a similar texture, some parts of the warp are occasionally worked into the fabric with much greater rapidity than others, while the tension on all should be the same. This circumstance renders it necessary to provide a means of producing the proper tension upon the threads, and to provide also for regulating the delivery of the yarn as it may be required. The yarn, instead of being rolled upon a yarn beam, as in the case of ordinary weaving, is placed upon bobbins which can deliver independently of each other. Letters patent have been granted within the last year for a mode of accomplishing the objects above mentioned, which will be understood from the following description, which is nearly in the words of the inventor:

"The nature of my invention consists in suspending a weight on the yarn forward of the spool or bobbin, which is so arranged as to unwind the yarn at intervals, as the slack is taken up by means of a catch which holds the bobbin from turning till lifted by a weight.

"The spools are arranged in a frame in the usual way, and just in front of each spool two wires are fixed in the frame; the catch is formed of wire, the ends of which are attached to a thin plate, the position of which is over the wires above named, and extending from end to end of the spool. The wire curves downward at each end of the spool to a point just behind it, where it is coiled round a pin forming the fulcrum for it in the frame; from thence it is bent upward and crosses over behind and parallel with the spool, and resting against it; from the rim of the spool project one or more pins that strike against the wire; this prevents the spool from turning to unwind the yarn. The yarn runs from the spool forward over the wire, nearest to the spool, and thence it passes down to the weight that is suspended by it, and from that over the other wire to the shed; by this, it will be obvious that as the slack yarn is taken up the weight will be raised, and when the yarn is let off from the spool it will fall, and all the time continue to keep the yarn stretched with an equal tension. The weight consists of a ball or other shaped poise, from which a rod projects; about the middle of the length of this rod is a flattened enlargement, through which there is a hole, and from this a slot is cut diagonally downwards, thus forming a hook by which the weight is hung on to the yarn, and leaving a portion of the rod to project above it. When the slack of the yarn is used up, as above named, and the weight is raised, the upper end of the rod passes up between the wires, strikes against the plate above, and raises it; this relieves the pin on the spool from the catch, and allows the spool to turn which lets off yarn, and

causes the weight to descend; the catch, being again brought into contact with the spool, stops its revolution as it comes round.

"It will be obvious that the arrangement of the bobbins in the frame or creel can be varied, as well as that of the catches; for instance, placing them endways towards the loom, or vertical, and so adapting the catches or weights as to act in that position without changing the general principle.

"What I claim as my invention, and desire to secure by letters patent, is the combination of the weight and catch with the bobbin or spool, constructed and arranged in the manner and for the purpose substantially as herein set forth; so that when the weight is drawn up, it will relieve the catch, and allow the spool to unwind and the weight to fall."

Felting.—One patent has been granted this year for felting cloth. The process and machinery used are but slight modifications of those well known.

Cotton batting.—Within a few years this article has become an important and extensive branch of American manufactures, and has recently drawn to itself the attention of inventors to such a degree that four applications have recently been passed for improvements in its manufacture. The bat of the required length and thickness being formed, by any convenient process, it becomes necessary to cover it with a thin coat of size; after which the fabric is dried. The extreme delicacy of the bat, and the very slight adhesion of the fibres to each other, render the process of sizing and drying one of considerable difficulty. The improvements made by three of the patentees I will give you in the words of the inventors, as extracts from the patents will present them clearly and concisely. The earliest of the four patented improvements will be understood by a perusal of the following extract taken from one of the other patents:

"The nature of my invention consists in arranging the sizing rollers immediately above an aperture in the top of a drying chamber, provided with a stove and hot-air tubes on each side to dry the batting as it descends, a grating on each side to protect it from contact with the tubes and stoves, and a folding box at the bottom, into which the batting is folded from one side to the other, as it descends. By this arrangement, I dispense with the endless belts heretofore employed in sizing and drying batting, which are soon destroyed by the great heat to which they are exposed in passing through the drying chamber, and which are, of course, very expensive; and, at the same time, I avoid the contact of the batting after it has been sized and before being dried. I am aware that it has been essayed to dispense with the endless belts by passing the sheets of batting from the sizing rollers over another roller, then down into the drying chamber, down near to the bottom of the chamber, and then up again to another roller at the top, the chamber being provided with a stove on each side, and a hot-air tube between the descending and ascending portions of the sheet of batting; but I consider this objectionable, for the reasons that the sizing vats and rollers are so situated that the sized bat has to pass over a roller before entering the drying chamber, and because, as it is carried down and then up again, in case of breaking it is liable to fall on to the bottom stove, and catch and communicate fire to the whole establishment; and in the event of not catching fire, it becomes necessary for the operative to enter the hot-air chamber, which is heated to a very high tem-

perature, to replace the batting in a condition to continue the operation up; all of which difficulties are obviated by the location of the sizing rollers immediately over the aperture in the top of the furnace, in combination with the arrangement of stoves and pipes, and protecting grates on each side, and the folding box at the bottom."

"I do not claim as my invention conducting the bat from the sizing rollers to the dying chambers without a belt; but what I do claim as my invention, and desire to secure by letters patent, is the arrangement of the vatch of the sizing rollers immediately over the aperture in the top of the drying chamber, in combination with the arrangement of stoves and pipes and protecting grates on each side of the chambers, and the folding box at the bottom, for the purpose and in the manner described."

The following is the third mode above alluded to, and is extracted in the words of the inventor:

"The methods heretofore practised of making the bat of the desired thickness for wadding are, to deliver the broad sliver or sheet of cotton from one carding engine into an apron, which moves back and forth until a sufficient number of layers have been obtained; or so to construct the engine as to deliver a single sliver, or sheet of the required thickness, or to carry up the slivers from the carding engines vertically, so arranged as to unite them all into one bat. The defects of these methods are obvious; for, with the first, the sheet of wadding must either be made very short, or be spliced end to end, (a very imperfect operation;) with the second the reciprocating apron, on which it is delivered, must be of an enormous length, occupying an amount of room too great for the convenience of an establishment; and with the third, the slivers, which are drawn up over head, frequently break. The arrangement of belts must necessarily be very complex; and from their situation, the slivers are much exposed to fire; and, indeed, from the number of accidents which have occurred, none of the establishments which manufacture cotton wadding can be insured. The object of the first part of my invention is to avoid these objections and inconveniences; and it consists in ranging a series of carding engines, one behind another, over an apron which has a continuous movement, so that the sliver or sheet of cotton from the second card is delivered on top of that from the first, the one from the third on to that of the second, and so on to the end of the series, the number of carding engines being in proportion to the quality and thickness of the bat or wadding desired; it being a fact well known to those versed in the art of working fibrous materials, that the thinner each sliver the more perfect will be the bat; and it will be evident that, with my method, this can be refined to any desired extent.

"As to the glazing operation, but one method has been practised, (although several have been proposed and patented,) which consists in conducting the bat on an endless apron to a vat, where it is glazed on one side, and then conducted to a second vat to be glazed on the other side, and from this delivered on to another endless apron, which passes through a kiln or hot-air chamber to be dried. This method is not only very imperfect, but attended with great expense and danger, for that face of the bat which rests on the apron is not exposed to the direct action of the heated air, and therefore dries slowly; which fact renders it necessary to raise the temperature of the kiln and hot-air chamber, which very soon destroys the apron, and often subjects the whole establishment to loss by fire.

The second part of my invention, it is believed, obviates all these objections, and consists in passing the glazed bat or wadding from the glazing apparatus through the kiln or hot-air chamber over a series of open reels, arranged side by side on one plane, and extending from end to end of the kiln, one reel delivering the bat on to another, and so on to the last in the series, where it is delivered out. If the bat is glazed on both sides before it is introduced into the kiln, but one set of reels is used; but I prefer to glaze it first on one side, dry this by passing it through the kiln on one set of reels, and deliver it at the other end to the second glazing apparatus, to be glazed on the other side, and then passed through the kiln on another set of reels above the first. In this way I avoid the inconvenience of accumulating the glazing or sizing on the rods of the reel, for, in passing through the first time, the unglazed surface rests on the bars of the reel, and the second time the side first glazed; in this way I avoid what otherwise would be a serious inconvenience."

"It will be obvious that the first of my invention is applicable to various operations in the manufacture of fibrous and textile substances, such as making bats of wool, and other animal fibres for felting, and all other operations in which it is necessary to form a bat of several thicknesses of sliver, of the width of the doffer of a carding engine; and it will be equally obvious that the second part of my invention is also applicable to all operations in manufactures which require fragile webs or tissues to be conducted from sizing or glazing apparatus, to be exposed to the action of heat or currents of air."

The following is the last process for glazing cotton batting which has come to my notice, and is in the words of the inventor:

"Pelisse or cotton wadding, which consists of delicate fibres of cotton connected together and made into a bat by the operation of the carding engine, has heretofore been glazed on the two surfaces by passing first one and then the other surface in contact with rollers or belts covered with the glazing matter, as it was supposed that this could only be effected by moving the surface of the bat in contact with a glazed surface. This necessarily requires two operations to glaze the two surfaces, and leaves the edges only partially covered or glazed, and consequently ragged and liable to fray out.

"My improved process avoids all these difficulties, and renders the operation much more rapid. It consists in passing the batting or bat into and through the glazing matter, and at a velocity so great as to simply cover the entire surface, including the edges, and prevent the glazing matter from penetrating to the inner fibres.

"The manner in which I have applied my improved process is simply to pass the batting, at a velocity of about thirty-six feet per minute, into and through the glazing matter, and under a roller near the bottom of the vat, and thence out, so that the batting shall pass through the glazing matter in passing to and from the roller.

"I wish it to be distinctly understood that I do not lay claim to this apparatus as it has been employed for saturating with tar, and other similar substances, batting made of hempen and other coarse fibres, employed in sheathing vessels, &c., the object being thoroughly to saturate the fibres to cause them to adhere to each other and to the cementing matter, with the view to form, as near as practicable, a water-proof fabric, the object and the fabric being entirely different from cotton or pelisse wadding; but

what I do claim as my invention in the process of glazing the fabric known under the general appellation of pelisse or cotton wadding is passing it through the glazing liquid at a velocity substantially such as herein described, so as to cover the entire surface and edges without penetrating to the inner fibres, as described."

Here I must close my remarks upon fibrous and textile fabrics. Neither the time nor space properly at my command will justify a more extended view of the subject. Enough has been said to show clearly that this important class of manufactures is still progressing in a manner highly creditable to the industry, enterprise, and inventive genius of this country.

STEAM AND OTHER GAS ENGINES.

This class includes not only steam engines properly so called, but the heating apparatus by which the steam or gas is generated for their propulsion, and the apparatus by which the steam is condensed. Sixteen patents have been granted within the year for improvements belonging to this class; some of which are, in my opinion, very important.

Steam generators.—Letters patent have been granted within the year for an improved boiler, adapted more particularly to the western waters, to obviate the difficulties arising from the deposite of sediment in various parts of the boiler. The fire chamber is placed at the side of the boiler. The boiler is composed of vertical tubes, surrounded by a large vertical cylinder, into the upper and lower parts of which they open directly. The bottom of this large cylinder is made dishing, and has a mud valve at the centre. The heat is first applied at the upper parts of the tubes, and afterwards carried around to the lower part of them, but not to the bottom of the boiler. The water enters a water jacket surrounding the fire chamber and the tubular part of the boiler, and as it is comparatively cool when it enters, it will sink down and enter the tubes at the bottom, to supply the evaporation which takes place at their upper ends. The current of fresh water, therefore, tends constantly to wash the sediment downwards towards the mud valve, while the evaporation is going on above. The value of this invention can be ascertained by experiment only.

Several modes of supplying water to boilers have been patented; and one very ingenious method I should be glad to notice, but I cannot give an intelligible description of it without drawings.

Four patents have been granted for safety-apparatus for steam boilers during the year. Three of them open a safety-valve by applications of the well known fact that different metals expand in different degrees by the application of the same amount of heat. As they present no strongly marked novelty, my limits will not allow me to give them further notice.

The fourth patent above referred to is for a magnetic gauge to indicate the height of water in the boilers. The construction and operation of this instrument are very simple, and will be fully understood, both in character and importance, from the following preamble in the words of the inventor:

"The importance of a reliable means of indicating the height of water in steam boilers is now universally admitted by engineers, for the reason indicated by science and established by experience, that the deficiency of water in boilers is the principal if not the only source of explosions; and hence the many attempts which have been made to obtain an apparatus

for this purpose, which, whilst it can be relied on, will at the same time be in such a condition as to insure the observance of the engineer. But, so far as I have been informed, all the attempts heretofore made have failed, because of the difficulty of forming the connexion between the water inside the boiler and an indicator, which, to be practically available to the engineer, must be outside. A float resting on the water, and communicating with an index, a lever, or other device outside, through a stuffing box, has generally been resorted to, but it is evident that the friction of the stuffing box will prevent the working of such an apparatus, which must be sensitive, and which necessarily possesses very little power, as the buoyancy of the float is its only actuating force. To avoid this difficulty, attempts have been made to put the indicator within the boiler by covering it with glass, but with as little success, for the action of high temperatures, it is known, renders the glass opaque.

"My invention, it is believed, will avoid all these difficulties; and it consists simply in attaching a magnet to the axis of motion of a wheel or lever, to which the float is suspended or attached, to communicate motion, by attraction and repulsion, to an index needle turning on an axis outside the boiler, and separated from the magnet by a steam-tight plate."

An important improvement has been patented within the year, in the mode of coupling or connecting two cranks, which are to operate in concert, and constitute what is known as the "bell crank" used on the main or other shaft of the steam engine and elsewhere. It will be readily perceived that any irregularity or inequality in the action of the cranks, which would in the slightest degree change the relative positions of the two, would produce a strain upon them, and the pin connecting them, which would soon cause one or the other to break, or would otherwise embarrass the action of the machinery. To obviate these evils the patentee has invented a new mode of coupling the cranks. The description cannot be fully understood without drawings; but the general principle may be understood from the claim, which is as follows:

"It will be obvious that the effect may be produced on the same principle by connecting the pin to one crank by a turning joint only, and in the other by a turning and sliding joint; and that the construction of the parts, and the manner of making these joints, may be varied without affecting in any manner the principle or character of my invention, although I have described that mode of construction which I deem to be the most effective, and best adapted to the end in view.

"What I claim as my invention, and desire to secure by letters patent, is connecting a crank pin with two cranks by means of turning and sliding joints combined, whether the pin be made to slide in both cranks or only in one, so as to equalize the strain of the engine on each crank, and allow them to move and compensate for any error in the relative position of the crank shafts, as herein described."

A valuable improvement has been patented, within the year, in the mode of connecting the cylinders of steam engines with the steam boxes. The "nozzle," which always causes a waste of steam, has heretofore been considered indispensable; but, by a judicious arrangement, the patentee has dispensed with it, and in other particulars has rather improved than impaired the connexion of the steam box with the cylinder. His invention will be understood by reference to the following extracts from his patent:

"In forming the connexion of a steam cylinder with the steam chest of puppet valve engines, it has long been known to engineers that the closeness of this connexion is important in an economical point of view, not only on account of the weight and cost of materials employed in making a long connexion, but because all the steam contained in this connexion is condensed or otherwise lost at each stroke of the engine, and hence various devices have been resorted to by engineers to surmount this difficulty. The steam chest has been variously arranged and located, but still all these devices have presented a large area between the chest and the cylinder; for, the steam chest being cast separate from the cylinder, sufficient room must be left to form the connexion by bolted flanches, which necessarily occupy much room.

"To remedy these evils is the object of my invention, the nature of which consists in casting the steam chests in one piece with the steam cylinder, or one with the cylinder, and the other with the condenser and the cylinder bottom, by making the side of the cylinder the side of the steam chest, and so of the condenser, and also in so forming and adapting the appendages of these parts as to enable them to come together and to unite the cylinder head with the cylinder, and the cylinder bottom with the cylinder within the narrow compass left between the steam chest and cylinder, when they are brought in such close proximity; the flanche on the cylinder and cylinder bottom being dispensed with towards the steam chest, and, instead thereof, a joint made between the chest and cylinder by packing or driving, and screws inserted from the inside of the steam chest and screwing into the solid metal of the cylinder; for the lower steam chest and for the upper end recesses being made in the side of the steam chest, to admit the requisite screw bolts for securing the cylinder head.

"I do not claim letters patent simply for casting the steam chests with the cylinder, or with the cylinder bottom and condenser; but what I do claim as my invention, and desire to secure by letters patent, is casting the steam chests with the cylinder, and the other with the cylinder bottom and condenser, by making the side of the steam chest the side of the cylinder or condenser, in combination with the manner of fitting the cylinder head and the lower end of the cylinder to the chests, and the mode of making the attachments without the continuation of the flanches, thus dispensing with the nozzle and nozzle flanches, and their attachments, and saving at each stroke the steam contained in the nozzels, all as herein described."

The mode heretofore adopted of tripping the drop cut-off valve, was, in practice, found to be imperfect, as, at certain points of the stroke, it could not be operated with certainty, and much injury would result from failure. Letters patent have been granted, within the year, to the original inventor of this cut-off, for an improvement which removes the practical imperfections of the old apparatus. The evil which existed, and the remedy, will be understood by reference to the following extracts from the new patent:

"By the method now practised of operating the drop cut-off valve, the motion is derived from the lifter, which approaches its state of rest as the piston of the engine approaches the middle of its stroke, or its maximum velocity; and the valve is tripped by the same motion which lifts it, so that there must be very great nicety in the adjustment to regulate the extent of the cut-off at about the half-stroke. The object of my invention

is to remedy this, and its principle or character consists in tripping the valve by a motion independent of the motion of the lifting rod or rods; and, also, in combining the various parts in such manner as to regulate the cut-off with accuracy during the action of the engine, by connecting the two shafts that trip the two cut off valves, end to end, by means of adjustable spring arms that take into, and are, when set, held in the teeth of a sector, which vibrates on the axis of motion of the shafts, and receives its vibratory motion from the eccentric; which spring arms may be shifted in the teeth of the sector, brought nearer to, or farther from, each other, and thus cut off at a less or greater portion of the stroke.

"It will be evident, from the foregoing, that any motion derived from any part of the engine may be substituted for the vibration of the arms or wipers, provided the character above described be maintained; as, for instance, instead of the horizontal vibrating motion of the arm or wiper, the spring may be disengaged from the stem of the valve, by a vertical descending motion, as the lifter rises; and this may be derived from any moving shaft, such as the piston rod, the beam, the crank shaft, &c.

"What I claim as my invention, and desire to secure by letters patent, is tripping the drop-valve of the cut-off by a motion independent of the lifters, substantially in the manner and for the purpose herein described.

"I also claim combining the wiper that drops the valve of the cut off, whether working horizontally or vertically, with any of the moving parts of the engine, other than the lifters or their rocking shaft, by means of the sector and arm or arms, by means of which the extent of the cut off can be regulated at pleasure during the action of the engine, from the full to the least portion of the stroke, as herein described."

The great advantages which result from working steam expansively have given rise not only to cutting off the steam at any desired point of the stroke, which is the object of the drop and many other valves, but also to the use of two cylinders; in the first of which the steam is admitted and operates in the usual way, and at the return stroke the steam at the exhaust end of the cylinder is admitted into the other cylinder, which is auxiliary to the first and of greater diameter, in which it operates expansively. Several modifications of this variety of engine have been from time to time invented in this country and in Europe, but they have not been extensively used. One of the most serious objections to them has always arisen from the fact, that while the steam was operating advantageously in the auxiliary cylinder, it was re-acting against and resisting the motion of the piston in the primary cylinder. This objection seems to have been entirely removed by a new arrangement of parts, for which letters patent have been granted within the past year, and of which the following is a general outline.

The two cylinders have the same length and diameter and are placed side by side with valves at each end, opening directly from one to the adjacent end of the other. The connecting rods of their pistons are jointed to cranks on the main shaft which are at right angles to each other, so that when one piston has completed its stroke the other is at half stroke. Suppose, then, the piston of the main cylinder to be nearly at the bottom or starting point; the steam is admitted in any convenient way to the main cylinder, and its piston moves until it has made its half stroke, at which time the piston of the auxiliary cylinder is at the bottom. The valve between the two cylinders behind the main piston is then

opened, and the steam expands into the auxiliary cylinder and operates behind both pistons until the first has made its full stroke and the second is at half stroke. The valve between the cylinders is then closed and the eduction valve of the main cylinder is opened, and the induction valve is opened at the other side of the main piston; at the same time the pipe to the condenser is momentarily closed, and the exhaust steam, lifting a hinged valve, rushes into the heater. The pipe to the condenser is immediately opened, and the remainder of the steam in the main cylinder is condensed in the usual way, and the main piston begins to return. In the mean time the steam which was left in the auxiliary cylinder is operating expansively upon the second piston, which it continues to do until it has completed its stroke, and the steam is then exhausted in the usual way, when the valve between the cylinders at the other end is opened, and the same operations are repeated during the return stroke which took place during the first. By this arrangement it is readily seen that the reaction above alluded to is entirely avoided, and that when the first crank is at its dead point the second is perpendicular to the second piston. Letters patent have recently been granted in England for an engine very similar to that above described.

Patents have been granted this year for modifications of cut-off valves, which it is unnecessary to describe.

The vibrating engine, for driving spiral propellers, patented in 1844 and noticed in the last report of my predecessor, is said to have presented practical objections, and letters patent have been granted within the last year for modifications, by which, it is said, they are removed. The improvement is certainly ingenious, and will be fully tested.

Important improvements in the rotary engine have been made and patented during this year. The usefulness of this variety of engine has been seriously circumscribed by mechanical obstacles in the way of its construction, which seemed to be incident to its nature; and among which the great extent of packed and ground surfaces was not the least. For many purposes the rotary engine is very important, and substantial improvements upon it have long been demanded. Such, in my judgment, is the character of those last patented. It is impossible, without drawings, to give a clear idea of the invention alluded to, but the following extract from the patent will sufficiently set forth its general characteristics:

"The characteristics of this engine, and what distinguishes it from all others before known, are, first, making the annular chamber in which the piston works (technically termed the "cylinder,") in two parts, united at a line passing through the centre of the annular chamber, and parallel with the axis of the shaft, instead of uniting the two valves at a line at right angles to the axis; by which arrangement I am enabled to make the cylinder true, less liable to unequal expansion, avoiding the necessity of a continuous packed or ground joint entirely around the chamber or cylinder, and presenting the important advantages of greater solidity and simplicity, the lower half being permanently fixed in the frame which supports the bearings of the shaft, &c., by flanches which admit the induction and eduction valves; thus greatly reducing the number of packed or ground joints, so objectionable in all steam engines, particularly the rotary engines.

"This arrangement not only adds greatly to the strength of the whole structure, but enables me to bore out the cylinder by an instrument, which,

during the operation, has its bearings in the boxes intended for the shaft of the piston, to insure accuracy in all the parts.

"Secondly, in so arranging the steam and exhaust valves, and the steam passages in the disk to which the piston is attached, as to avoid the pressure of steam on the valves when moving; and connecting these with a shifting valve which governs the apertures in the disk and the one on the hollow shaft, through which the steam is admitted, and an annular groove in one of the packing plates that covers the disk, so as to afford an easy and simple mode of reversing the action of the engine.

"Thirdly, in grooving the faces of the disk and of the packing plates or cheeks between which it works from the outer periphery inward, to admit steam to lubricate the rubbing surfaces.

"Fourthly, making the outward and rubbing surface of the piston of a single spring-metal hoop, divided at its junction with the disk, so that by means of hempen or other packing within and a packing head, the diameter of this ring can be enlarged and diminished at pleasure to fit the cylinder, by which means the numerous joints found in metal pistons heretofore used, and which are so objectionable, are avoided.

"And, lastly, connecting the piston to a flanche projecting from a disk on the shaft, by means of screws, passing through enlarged apertures in the disk, to admit of the free play of the piston, to adapt itself to the cylinder in case of any inaccuracy."

In closing my remarks upon this class of inventions, I deem it proper to express the opinion, that, during the six years of my connexion with this office, no one year has been signalized by so many truly valuable inventions connected with the steam engine as the last.

NAVIGATION AND MARINE IMPLEMENTS.

But few inventions have been presented to this office, during the year, upon the subject of ship or boat building. One invention, relating to the movable keels of vessels, has been patented. The bulk-head, in an important part of the hold, which is necessary for the reception of the slip or sliding keel, causes much inconvenience in lading, and considerably diminishes the capacity of the vessel. To obviate these inconveniences, the patentee places the movable keel in the proper position upon the outside of the vessel, where it is retained by bolts passing down into it, through the pillars which support the middle of the thwarts, and through the bottom. Chains also pass in like manner, to the top of the keel, to draw it up and hold it tight against the bottom of the vessel, and which have sufficient length to allow the keel to be drawn up the side of the vessel and out of the water. Other chains are attached to the keel, which pass up by the side of the vessel, for drawing it up out of the water, when, by the withdrawal of bolts and loosening of the other chains, the keel is unshipped. I make no remark upon the probable usefulness of this invention, but shall leave it to practical men.

One patent has been granted for an improvement in the construction of iron boats, which is worthy of attention, and which will be understood from the following extract taken from the patent:

"My invention consists in forming the sheets of metal with mouldings or beads, in suitable places to take up the surplus metal, when said plates are pressed into form, by means of projections on the die and correspond-

ing depressions on the matrix or concave mould, which gather up the metal and prevent wrinkles around between the upper and lower parts of the boat, so as to present a smooth surface, and also in forming a recess or bed for the gunwale, which holds it in place, and prevents its getting knocked down. I also add a flanche around the stem and stern posts, and along the line of the keel which takes up the surplus metal there, and forms the keel and stem and stern posts."

One patent has been granted for improvements in sails, by which, it is said, cotton canvass can be successfully substituted for that which is in common use.

A truss has long since been used to sustain the yards of vessels, but when applied to any of the lower masts, it becomes necessary to unship the yard before the mast immediately above it can be lowered. To remedy this inconvenience, a truss has been invented and patented within the year, so constructed that the upper mast can be lowered directly through the truss, without disturbing either truss or yard.

The injurious effects of the booms and gafts of mainsails, foresails, &c., upon masts, have induced ship builders to resort to various expedients for avoiding them. Friction rollers, slides, &c., have been placed in the jaws of the boom or gaft. Slides have been used with some success; but when applied to the boom jaws, the slides, by resting upon and striking against the saddle, soon become bruised and broken in such a manner as to injure rather than protect the mast. Letters patent have been recently granted for a means of avoiding this difficulty, which consists in so constructing and supporting the saddle, that a space is left between it and the mast for the reception of the slides, while the boom rests upon the saddle in the usual way.

Letters patent have been granted, within the year, for a cable spring, to be used when ships are riding at anchor. Its object is to prevent the violent and injurious jerks and strains which are caused by the motion of the vessel. The machine consists of a long wedge, placed between two rollers in a frame firmly fixed. The rollers are pressed together by powerful springs, for the purpose of resisting the passage of the wedge between them. The cable is then attached to the wedge, sufficient slack being left between the wedge and the capstan, and when any strain comes upon the cable the wedge is drawn in between the rollers as the springs yield, and is forced back by them when the strain is removed. By this device allowance can be made, by a comparatively small contraction of the springs, for a very considerable motion of the vessel.

Propellers.—Applications for letters patent for improvements in propellers have been very numerous during the year, but most of the alleged inventions which have been presented were old, and of course rejected; and, with few exceptions, those which have been patented possess very little novelty or usefulness. The applications have extended to almost every class of propellers, but principally to that variety known as the "*screw*" propeller. As they present no striking features to distinguish them from others which are well known, it is unnecessary to go into a detailed description of them.

The spiral propeller, although among the best submerged propellers now in use, is subject to a very serious objection; an objection which cannot be removed, as the defect is incident to, and inseparable from, the very nature of the propeller. And it is this: when the propeller revolves,

only a portion of the force, which it derives from the engine, is exerted to propel the vessel, the remainder being lost in lateral pressures, which produce no beneficial effect; and, indeed, it is well if they do no harm. It will be readily perceived that, if the floats were at all points parallel to the shaft, the whole force would be exhausted in lateral pressures, and no part of it would be exerted to propel. If, then, the floats are placed in a position slightly angular to the line of the shaft, a slight propulsive force would be produced, but a diminished lateral force would still be exerted; and, as the angle of the float increases, the relative proportions of these forces will vary until the floats become perpendicular to the line of the shaft, when no power, propulsive or lateral, is exerted. It is only in positions between these extremes, and partaking more or less of both, that propulsive power is attainable, and in such positions the lateral force is also exerted and lost. By the well known mode of resolving forces, the force exerted by each float may be decomposed into two—one in the direction of the shaft, and the other perpendicular to it; the former, alone, would exert a beneficial influence, and the latter would be lost. If the angle of the float is such as to produce very little lateral pressure, an impracticable velocity of the propeller would be required to produce a reasonable degree of speed in the vessel, so that no position of the floats will answer a practical purpose which does not waste a great part of the power in lateral pressures. However the floats may be formed, this objection will still, in one way or another, cling to them. And, as economy of power is of the utmost importance, particularly in sea-going vessels, where the submerged propeller is especially necessary, it is highly important that a propeller should be introduced whose action is direct, and which is not incumbered with those practical inconveniences which have impaired the usefulness of most of those which have hitherto been essayed.

CIVIL ENGINEERING AND ARCHITECTURE.

No improvements in architecture have been brought to my notice, in the discharge of my duties, during the past year, except in the minor branches, such as improvements in the mode of constructing and hanging doors, windows, &c., and preventing the entrance of water under them during storms. As these improvements are mere modifications of the modes heretofore in use, and well known, it is not important that I should describe them.

Civil engineering.—A very considerable number of patents have been granted in this class during the year; and while some branches of it have advanced less than during the preceding year, others have made greater progress.

Hydraulic foundations.—The screw-pile invented and patented some years since in Europe, but which until recently has not been extensively used, the inventor has caused to be patented in this country. Its usefulness for hydraulic foundations and moorings has come to be understood in Europe, and it will probably soon be equally well appreciated in this country.

Letters patent have also been granted for an improvement in hydraulic foundations of an entirely different character. It is well adapted to sandy bottoms, and calculated to obviate the great evils consequent upon the washing away of the sand, and thus undermining the pier upon which

the wharf or other superstructure rests. From the following, nearly in the words of the patentee, the invention will be understood:

"To construct a circular foundation.—A platform of temporary piling is first erected upon the site for the convenience of the workmen. An iron pile, (wrought) of suitable length and diameter, and armed with one of Mitchell's patent screws at its lower extremity, is inserted into the ground or bottom, at a point occupying the exact centre of the intended structure. This forms the guide-pile, to regulate the placing of all the other parts of the structure. A series of similar wrought-iron screw-piles are then inserted into the ground or bottom, at exactly equal distances each from the centre guide-pile, and at exactly equal distances from each other, forming, of course, so many points in a great circle. Between each pair of piles so placed is next inserted a segmental piece of cast iron, termed a bed socket. One of the segments being placed between each pair of piles, and resting its angular edge upon the ground or bottom, forms consecutively a circular, grooved, and socketed surface to receive the parts of the superstructure, as follows: Upon each pile is now fitted a tubular piece of cast iron, with projections at opposite sides. The lower end of this tubular casting fits into the socket of the bed plate, and the projections on its opposite sides form a perpendicular groove, in which are received the edges of the pannels, and which pannels and tubular pieces have a uniform circular surface. The shell of the foundation is then completely formed, and is now strengthened by a series of tension rods hooked on to the several tubular pieces and other parts, if found to be necessary, and all these tension rods are set up to the centre guide-pile by means of swivel screw-joints. The cylindrical cast iron shell thus formed is then to be filled in with stone, concrete, or other filling, as may be found expedient.

"To protect the bed sockets aforesaid from being undermined and disturbed from their proper level, by the action of tidal currents, I adopted the following plan: As soon as the circle of iron piles is completed, I put down outside thereof a complete circle of pieces of cast iron, say six feet in length and diameter, of a converse segmental form; and these segments are all shackled together by bolts passing freely through hinge bosses cast on their inside angles. Two or more of these concentric circles of these segments are thus put down, either by means of a diving bell or other hydro-pneumatic apparatus, and it is apparent these segments, when undermined by the action of the current, will descend, generally, and thereby enclose and protect the surface which they respectively cover. It is assumed, also, that these segments will so deflect the tidal current from the main body of the work, about its base, that no process of undermining can take place; though, as an additional security, the spandrels between the converse surfaces of these segments should be filled in with clay or stone as soon as the bed plates are fixed in position. In another form of these segments for protecting the bottom from abrasion, it is proposed to cast it as a hollow box, whose transverse section should be triangular, with hinge bosses for shackling the pairs together. This form would more effectually exclude the water from acting upon the surface enclosed by these segments.

"The application of this mode of forming the shells of piers, breakwaters, &c., where the plan is rectilinear instead of circular, must be obvious without details."

Dredging machines.—Two patents have been granted within the year for machines of this class, intended for the deepening of channels, &c., and two for excavating and ditching. One of these patents is for an improvement upon those dredging machines which effect their excavations by a scoop, having a long handle by which it is thrust down, and is afterwards filled and elevated by a proper arrangement of blocks and rigging, by operating which the proper motions are given to the scoop. The mast with which the rigging is connected has heretofore been stationary; but the patentee, believing that the operation would be facilitated thereby, has arranged and properly supported the mast upon circular rails, by which it is made movable, and the operations of the machine extended.

The other dredging apparatus is intended to operate upon a large scale, and will be understood by the perusal of the following claim which was granted to the patentee:

"What I claim as my invention, and which I desire to secure by letters patent, is the before-described mode of scraping the bottoms of rivers by operating a floating scoop by power machinery, placed in a separate vessel anchored on the opposite side of the river, said floating scoop being attached to an anchor up stream, so that the current will carry back the scoop to the opposite side of the river at the termination of every operation of the said scoop for a repetition of the scoop; the vessel containing the engine being moved up or down stream, as the work progresses, by the power of the engine, as described."

One of the ditching machines patented consists of a series of cutters, such as have heretofore been used for cutting and forming the sides of the ditch, in combination with a scraper which follows them for cutting the bottom and conveying the excavated earth to the side of the ditch, and firmly depositing it there. The edge of the scraper is in a common form, but the body of it is warped or twisted in such a manner that, as the excavated earth passes along over its surface, it is so turned as to fall and be pressed upon the bank with the turf side next to and extending up from the side of the ditch. In the western prairies, where wood for fencing is difficult of access, these ditches and levées are valuable substitutes, and machines for constructing them with rapidity and economy are of very great importance.

A mode of raising sunken vessels or recovering their cargo has been patented within the year, which is said to have proved very successful. Circumstances are often such that it could undoubtedly be very advantageously employed. The description of the apparatus and mode of operating are as follows, nearly in the words of the inventor:

"The nature of my invention consists in the employment of a cloth or flexible caisson to surround the wreck for the purpose of excluding the surrounding waters, so that the water within the vessel and caisson can be pumped out, and in the employment of a frame or frames to be erected above the vessel for the purpose of giving access to any part of the vessel; and also in connecting with such cloth or flexible caisson a pump or pumps, suspended to a steamboat or other vessel carrying the motive force for pumping water from the caisson and wreck.

"The flexible caisson is made of canvass or other cloth, of sufficient size to surround and encompass, and extend sufficiently low to cover, all the leaks in the wreck. It should be made water-proof by any of the known means, and of sufficient strength, by repeated layers, to resist the pressure

of water. The lower edge is lapped over, or hemmed, to embrace a chain which extends entirely around, to act as a sinker, and enable the pressure of the surrounding water to force the cloth or caisson up to and under the bottom of the wreck.

"For the purpose of getting access to the cargo of a wrecked vessel, I employ in combination with the flexible caisson a frame, which I denominate a platform, the construction of which should be varied to suit the peculiar situation and condition of the wrecked vessel. I shall here set forth the mode most generally applicable. In the first place, I make a frame about twelve feet in length, and as wide as the wrecked vessel, enlarging the same if it becomes necessary in the operation of saving the wreck or cargo. The said frame consists of two bents placed twelve feet apart, and secured together by four girts, two at each end. When the frame is thus constructed, I attach it to the vessel by means of bolts, screws, chains, or other fastening, so as to render it a firm fixture to the wrecked vessel. The frame is then made to receive timbers and floorings, putting it in readiness for operations on the wreck.

"When the wreck is wholly under water, I build a temporary frame around the sides of the wreck, extending from the deck or uppermost part of the wreck above the surface of the water. When the wreck is only partially covered with water, the temporary frame may only extend around that part of the wreck which is submerged; and in case the upper part of the wreck is out of the water, but a part of it is stove in or broken, or is otherwise rendered so leaky as to interfere materially with the water being pumped out, I make the frame-work of such extent and in such places as may be required by the particular circumstances.

"The flexible caisson encircles this platform or frame as well as the vessel, and by this means access can be had to any part of the inside of the vessel for the purpose of removing any portion of the cargo, or closing up the leaks, if the intention be to raise the wreck."

Railroads.—Four patents have been granted during the year for improvements in railroads, and of these two are extensions of well known patents. The other two do not present striking novelties, but nevertheless the inventions appear worthy of attention. The objects at which the inventors seem to have aimed are permanence and simplicity. The following extracts from one of these patents will sufficiently set forth the nature of the improvement:

"I do not use either string-pieces or cross-ties of wood or stone, but I make them of iron. The lower portion of the string-piece, which I will call the under rail, has a broad bearing upon the road bed, and I connect them together laterally and longitudinally by means of iron cross-ties and chairs formed in one solid piece.

"The base of the under rails may be made ten or twelve inches wide, and threee-fourths of an inch thick. The stem which rises from the middle of the base may be seven inches high, and three-fourths of an inch in thickness. The top of the stem is enlarged where it is to receive and embrace the top rail. Along this enlargement of the top of the stem a groove or channel is formed, which is to receive, first a strip of hard wood, kyanized, or other elastic substance, and upon this is placed the top rail. The strip of wood may be about an inch thick, and the channel should be about an inch and a half deep, so as to embrace the base of the upper rail to the depth of about half an inch. The width of the channel should

be about two inches and a half, or of such width as may be rendered necessary by that of the top rail."

"Having thus fully described the nature of my improvement, and shown the manner of carrying the same into operation, what I desire to secure by letters patent is, the use of the continuous strip of wood, or other elastic substance, combined with the under rails, as described herein, and with the wrought or cast iron top rail, of the plate, or bridge, or any other form, substantially in the manner set forth.

"I also claim the manner of connecting and holding together the upper and under rails of iron, as herein described, so as to make the under rail serve as a *chair throughout its whole length* to the top rail, (the latter being imbedded in a channel in the former,) or, as in the other described plan, where the top rail is grooved on the under side, and rests on the under rail as a saddle, thereby giving strength and stability to the joints of both the upper and under rails.

"I claim the use of cast iron top rails, when in connexion with iron under rails."

During the past year the attention of engineers appears to have been more than usually drawn to the subject of ascending and descending inclined planes by locomotive power. Each particular locomotive requires slight modifications of the track, though I have seen none which presented patentable changes. There are few railroads upon which inclined planes are necessary; and it is to be regretted that engineers have heretofore thought it expedient to leave such obstacles in the way, to interrupt travel and transportation, and to tax their own ingenuity, their time, and their purses, in devising means of overcoming them. The inconveniences, delays, and expenses, resulting from these obstructions, would, in a few years, amount to more than would have been sufficient, at the outset, to construct the road in such a manner as to have avoided them, and allowed the ordinary locomotive, with its train, to move on quietly from one extremity of it to the other. More than the necessary expense of a proper construction is ultimately incurred, and still the delay and inconveniences must be submitted to, and the inclined plane still remains a monument of injudicious and shortsighted economy. But as they exist, trains of cars must ascend and descend them; and in another place I shall remark upon such improvements in locomotives as have been patented during the year for the accomplishment of this object, and will here, as connected with this subject, call your attention to an improved "atmospheric railway," for which letters patent have been granted in this country within the last year to a foreigner.

Notwithstanding the serious objections which have been urged against this mode of conveyance, any one of which would be sufficient to establish its inutility for general purposes, it seems recently to have attracted much attention, particularly in Europe; and it has finally been suggested that it may be rendered very useful in ascending and descending inclined planes. In my judgment this suggestion is a valuable one, and worthy of attention and experiment. The shortness of the tube, for this purpose, would be such as to remove, in a great measure, the danger of imperfections in it, and the liability to accidents, which can scarcely be avoided when the length is great. And, again, the parts can be so constructed and combined that the descent of one train of cars, while they are controlled by the atmospheric apparatus, will exhaust the tube, and thus prepare it

to become a powerful auxiliary in effecting the progress of the ascending train. Great perfection in the cylinder, or tube and piston, would of course be required. Thus it sometimes happens that an invention, which fails in its application to the purpose for which it was intended, may be successfully applied to purposes which, at the beginning, were scarcely contemplated.

The invention for which letters patent were granted, as above mentioned, is so described by the inventor that it cannot be understood without drawings. Its general characteristics, however, may be described as follows, viz: The tube is so constructed that it has no lateral openings, except into air-tight chambers. The piston has considerable length, and is furnished with a rack upon each side. In the lateral air-tight chambers, opposite these racks, are placed pinions working into the racks upon shafts which extend up through the top of the chamber, and upon which shafts pinions are placed, working into fixed racks upon the car which is to be propelled. At the top of each box, or air-tight chamber, a conical opening is made for the shaft, like a valve seat, and a conical collar to fit is placed at the proper point of the shaft, so that when the air is exhausted from the tube or cylinder the external air will press down the valves and keep the chambers tight. As the air is withdrawn from one end of the tube, the piston, by atmospheric pressure, commences its motion, the racks upon it take into the pinions upon the lower ends of the vertical shafts above mentioned, causing them to revolve, and with them the pinions on the upper ends of the shafts, which, taking into the racks on the car, propel it forward. The racks upon the piston, and those upon the car, are of such length, that, before they are disengaged from one pinion they engage with the next. When the head of the piston has passed the opening for the pinion, the shaft of the pinion is, by a suitable device, raised so that the friction of the valve upon the seat is avoided.

It is unnecessary to comment upon the merits of this modification of the "atmospheric railway," as I deem the general remarks which have already been made amply sufficient. The subject has been fully and ably discussed in the foreign journals.

Railroad cars.—Several applications have been made within the year for improvements in cars for ascending and descending inclined planes. Some of them are still pending, and upon one of the applications letters patent have been granted. The invention, however, presents but little novelty, and does not appear calculated to accomplish in practice all that the inventor contemplated. Public attention has been called to it through the papers and otherwise, and I do not deem a description of it necessary.

Locomotives of this kind are either such as are used on the inclined plane only, or such as are intended for use upon all parts of the road. When either kind is substituted for the stationary power, the expense of the track and its liability to derangement are much increased; accidents in ascending would certainly not less frequently occur, and the power must be sufficient not only to carry up the trains, but also the immense weight of the locomotive. When, therefore, the former or extra locomotives are thus substituted, the result must, in my judgment, present diminished security and increased expense. When the latter are resorted to, and the same locomotive is used for ascending inclined planes and for locomotion on all the other parts of the track, the obstacles are no less formidable. All the objections above mentioned are still incident to the

system, and, in addition, the locomotive must be much stronger and heavier in all its parts than is necessary or convenient on the level part of the road; and to this must again be added the great weight, expense, and liability to derangement, of the additional machinery *necessary* to the ascent of the inclined plane, but which increases liability to accidents on all parts of the track. When these circumstances are taken into consideration, and it is recollected that all these expensive incumbrances must be hanging about the locomotive, and impeding its progress for perhaps one hundred miles, and can only be made useful for half a mile, it will perhaps be concluded that inventive genius can be more advantageously exercised in some other branch of the arts than upon locomotives for ascending inclined planes.

Nine patents have been granted within the year for improvements connected with locomotives and railroad cars. Some of them could not be fully understood without drawings. They are for improvements in hanging car bodies so as the better to equalize the weight upon the wheels, and to give greater ease of motion; for an improved connecting link; for replacing cars which have been thrown off the track; for improvements in car wheels; for removing trucks by the use of a drop platform, and for a mode of connecting the wheels of locomotives, so that they shall all operate as driving wheels. It is not necessary particularly to describe them.

The anti-friction box for axles, &c., in which the axle, &c., turns upon friction rollers, has heretofore been liable to serious objections—which appear to have been to a great extent removed by an improvement patented within the year. The inconveniences heretofore experienced, and the inventor's mode of obviating them, will be understood by reference to the following extracts from his patent:

"The nature of my invention consists in providing the axle and box with beveled or mitred shoulders or collars, in connexion with anti-friction rollers, having the ends of corresponding form, to substitute rolling for rubbing friction at the ends of the rollers—as it is well known that in the use of anti-friction rollers in the boxes of carriages and other axles much friction in guiding the rollers, when made square or round as heretofore, has been unavoidable; but by this arrangement rubbing friction is entirely avoided, and rolling friction substituted therefor; and hence much jar may be avoided by keeping the flanches close up to the ends of the rollers."

"By thus beveling the ends of the rollers, and the shoulders on the axle and box, it will be obvious that where the bodies come together, in avoiding end play, the rubbing friction heretofore experienced is avoided, and rolling friction substituted therefor.

"I do not claim as my invention the employment of a series of rollers, connected by rings at each end around an axle, and within the box, as this has long since been done; but what I do claim as my invention, and desire to secure by letters patent, is making the ends of such rollers on a bevel or mitre, in combination with shoulders, collars, flanches, rings, or other projections on the axle and on the box or hub, having corresponding bevels or mitres to avoid the rubbing friction at the ends of the rollers, and the more effectually to prevent end play, substantially as herein described."

Bridges.—But one patent has been granted during the past year for improvements in bridges, and that was granted for a slight modification in

the mode of producing the camber, and need not be here described. Several applications for patents under this head have been made, some of which are still pending; but most of them have been rejected for want of novelty. For some years past, very few substantial improvements have been made in this branch of civil engineering. There are periods in the history of all the useful arts during which their progress appears to be suspended, as if they had already attained the full limits which science assigns them. But often, after a long interval of rest, during which all have followed tamely in the footsteps of their predecessors, some ingenious and original mind arises, boldly leaving the beaten track, and, as he explores untrodden paths by the light of his own genius, new wonders arise to mark and signalize his progress.

LAND CONVEYANCE.

Carriages.—Seven or eight patents have been granted during the year for improvements in carriages, wagons, and carts. Some of the inventions patented, such as self-acting cart bodies, &c., evince much ingenuity, but do not present that degree of practical utility which could be desired. In such vehicles as wagons and carts, a reasonable degree of cheapness, simplicity, and durability of all the parts are indispensable; and if these are lost sight of, it is immaterial how much convenience and saving of labor its extra and unusual fixtures may effect. The labor which such machinery saves is not very expensive, and is saved to very little purpose, as it cannot be otherwise usefully employed; while a derangement of the parts might render the whole inoperative, even with the assistance of the attendant.

The patents above alluded to are for improvements in wheels, in the hanging of carriage bodies, in axles, and in brakes. They are all slight modifications of devices long and well known, and I do not deem it essential that a description of any of them should be here given.

The most striking improvement patented within the year, in this class, is the prairie car. This invention is not presented with the noisy pretensions which frequently characterize the advent of new discoveries, but seems to claim for itself no more than experiments justify us in believing it can accomplish. It is not intended to rival the railroad system, where that can be successfully established and sustained; but it is intended for prairies, and other level and unbroken grounds, where no road is necessary to be built for it, and where the amount of travel and transportation will not justify the construction of railroads. Within these limits it promises great usefulness, as there are extensive regions in the west which present an appropriate field for its successful operations.

The prairie car consists of a frame of proper strength and dimensions to sustain the steam engine or other superincumbent weight. This frame, instead of resting upon ordinary wheels, is supported by hollow cylinders of a convenient diameter, and very wide tread. These cylinders are placed upon axles and constitute the driving wheels. The cylinders are made hollow, for lightness, and close, to prevent the entrance of mud or other matter, and the tread is very broad to prevent sinking into soft earth, &c. Two smaller wheels of similar construction are placed upon axles in a separate frame at one end of the car to guide it. This frame turns upon a pivot, by which it is connected with the main frame, and is ope-

rated by such means as are convenient for steering. The foregoing are the prominent features of the car or locomotive. The propelling power is applied to the driving wheels in any convenient way. There is much originality in the idea of traversing the prairies by steam cars, upon their natural and unbroken surfaces, and much merit in adapting the cars to the nature of this novel undertaking.

There is nothing further in this class which demands particular attention.

Mills for grinding, and machinery connected therewith.—Nearly twenty patents have been granted during the year for improvements upon the various kinds of grinding mills, and the machinery connected with them, including horse-powers. They have generally been granted for very slight and unimportant changes in the machinery, already well known, and are calculated to exert no considerable influence upon this branch of industry. Some of these improvements, however, are worthy of notice in this place. A few omissions will be necessary, however, from the fact that drawings are necessary to a clear understanding of the subjects.

Flouring mills.—Several patents have been granted for this variety of mill; one for pulverizing the grain in a kind of mortar, having a series of pestles, and regulating the discharge in such a manner that the flour cannot escape until it has become sufficiently fine.

Serious inconvenience frequently results from the heating of the stones by great rapidity of motion and friction. The flour becomes burnt and injured. Precautions against this inconvenience had already been taken, which were more or less effectual. Within the year, letters patent have been granted for a new mode of diminishing the heat. It consists of an air tube, extending entirely around the stone at the outer part of its grinding face, from which branches extend along the grooves in the face of the stone. The whole is connected with apparatus, such that a constant current of cool air passes through the tubes, by which the stones are to be kept at a proper temperature.

After grinding, the flour passes through a bolting machine, by which it is sifted, and the different qualities separated from each other. At the lower end of the bolt, the sifting medium is coarser than at the upper end, the upper end allowing only the finest flour to pass through into the trough below. A portion of the finest flour, however, will adhere to the coarser part, and pass down and be deposited with it, and thus constitute a portion of the inferior article. To save the fine flour thus liable to be lost, an improvement in the bolt has been made and patented, which consists of diagonal or spiral vanes or scrapers attached to its exterior surface, near the lower end, which, as the bolt revolves, scrape or carry a portion of the "middlings" up along the trough and deposite it in the tube through which it is conducted to the carriers, and passed a second time through the bolt. This operation is supposed by the inventor more perfectly to effect the desired separation.

Several patents have been granted for improvement in mills for cutting and grinding corn in the cob. They generally receive the cobs endwise, through the stationary grinder; and, by knives on one grinder and rests on the other, the cobs are cut into short pieces, which afterwards pass through the grinding part of the mill. These mills are but slight modifications of such as have been formerly used, and a more detailed account of them would shed no important light upon this variety of machinery.

Bark mills.—Several patents have been granted for improvements in mills for grinding bark, some of which are also adapted to grinding corn in the cob. The differences, however, between them and those formerly in use are so trifling that I do not feel justified in going into a description of them.

Letters patent have been granted for a coffee mill, (which, however, may be used for other purposes,) consisting of a conical cone, surrounded by a hollow cone, which is divided longitudinally into narrow sections, between which strips of steel are placed extending into the interior of the mill, and serving as teeth for grinding. On the outside of this hollow cone, and resting against the backs of the strips of steel, hoops are placed, which, by being contracted or moved towards the base of the cone, will force in, and thus lengthen the teeth, as they are found to be worn off. I have described this mill because of the peculiarity which it appears to present, but not with a view of expressing an opinion respecting its utility.

Horse-powers.—Applications under this head have been quite numerous during the past year, but most of them have been rejected for want of novelty. As the "horse-power" consists merely of the machinery which serves as a medium for communicating the power of the animal to the machine to be driven, it naturally follows that the field which it presents for the inventor to occupy is very limited. Narrow as it is, however, multitudes have for years been striving to gather laurels upon it; with what success, it is not difficult to judge *a priori*. But, notwithstanding the vast number of inventions and re-inventions which have been made in this kind of machinery, the subject does not appear to have been entirely exhausted. Five patents have been granted during the year, one of which is for improvements which render the machine so convenient, compact, and comparatively free from friction, that I deem it well worthy of notice. It is impossible to present a perfect idea of it without drawings; but the following extracts from the patent will convey a general outline:

"The nature of my invention consists in arranging two series of cog or belt wheels upon two sets of shafts; each wheel, with its pinion, being on a section of one of the shafts, and the sections of each shaft working one within the other, and running in the same direction, instead of the reverse direction, or upon permanent sleeves, receiving one section within and the other without; the advantages of which arrangements will be fully pointed out hereafter.

"By the arrangement of the two series of wheels upon the two axes, transferring the motion from the first to the second, then back to the first, and then again to the second, and so on to any number of wheels, the shaft of one wheel turning on the shaft within it, and (as the result of the arrangement of the wheels) in the same direction and with greater velocity, the friction occasioned by the turning of the outer section on the inner tends to carry it around, and thus greatly reduces the actual friction; but another important advantage resulting from this arrangement of the wheels, besides that of great compactness, is the relieving the shafts from much of the pressure, unavoidable, in the usual mode of gearing up.

"Having thus fully described the characteristics of my invention, and the manner of making and using the same, I wish it to be distinctly understood that I do not make claim to the employment of a series of wheels, having the same axis of motion when the sections of the shafts are separated from each other by a permanent sleeve, or without the sleeve, when

the arrangement of the wheels is such as to cause the sections of the shaft to turn in reverse directions, as these are well known, and do not attain the end contemplated by me and pointed out above; nor do I claim simply oiling a journal through a perforation in the shaft, as this has long since been known; but what I do claim as my invention, and desire to secure by letters patent, is the arrangement of two sets of cog or belt wheels, and pinions connected therewith, each set consisting of not less than two wheels, with their appropriate pinions, or two shafts made in sections, turning on each other, and in the same direction, for the purpose of avoiding friction, and rendering the machinery compact, as herein fully described.

"And I also claim, in combination with the arrangement of shafts herein described, the oil passages, whereby the oil, applied at two places, is conducted to all the rubbing surfaces of the series of shafts and bearings, as herein described."

I do not deem it proper to extend my remarks to any other inventions belonging to this class.

MACHINERY FOR MANUFACTURING AND WORKING LUMBER.

This class comprehends a great variety of machinery; but, as nearly all its branches have attained a high degree of perfection, fewer striking improvements are to be expected than in some of the other classes which are of more recent origin, or those which, in some of their branches, require greater nicety or complexity of machinery.

Saw mills.—Four patents have been granted, within the year, for saw mills: three for ordinary sawing of boards, &c., and the fourth for sawing irregular shapes. The former are for improvements in the carriage and apparatus for setting the log or making the mill self-acting. Saw mills have long since been patented, which, after the log is properly placed upon the carriage, the various parts of the machine adjusted, and the gate, which admits the propelling power, opened, will saw the whole log into boards of any one thickness required, and close the gate and stop the machinery after the work is done. This being the case, it will be readily perceived that, so far as results are concerned, but little remains to be done for the self-acting saw mill.

The improvements patented as above mentioned, are for modifications in the means of effecting some one or more of the above operations; but no new effect has been produced. The mills above alluded to, are too complicated to be understood without drawings; and, although useful, a minute description of them would add but little to the information formerly extant upon this subject.

Letters patent for an improvement in mills for sawing irregular shapes, such as blanks for gun stocks, &c., have been granted within the year, of which the following is an outline: An ordinary saw gate is arranged in the usual way for giving the up and down motion to the saw. The saw is connected to this gate by levers having their fulcra upon the top and bottom of the gate, which levers extend both in front and behind the gate. The ends of the levers opposite to those jointed to the saw are connected to each other by a rod. The carriage carries the plank to be sawed towards the saws in the usual ways. To this carriage grooved guides or patterns are attached, which are adapted to the shape to be sawed, and to

each other. Through sliding blocks in these grooves the saws work. With this arrangement of parts, it will be perceived that, as the carriage advances, the guide and block give the proper direction to the edge of the saw, and the levers permit the proper lateral motion. Thus, as the carriage moves on, the saw gate gives the saw its up and down motion, the levers allow its lateral motion, and the guide and block, through which the saw passes, give a proper direction to the saw. Any number of saws, similarly guided, may be used.

Planing machines.—Eight patents have been granted within the year for improvements in planing machines. One of them, however, was a mere reissue of the extended patent for the well known "Woodworth machine." This machine seems to comprehend all that is necessary for planing, tonguing, and grooving regular surfaces; and therefore inventors have not sought to improve it, but have confined themselves principally to the invention of such machines as may be substituted for it, or to those which perform other kinds of planing. The subject is vastly important, and no effort which ingenuity, prompted by interest, can make, has been spared in attempts to accomplish the grand object of producing a machine which, without infringing the patent, may be successfully substituted for the "Woodworth machine." Whether the machines patented infringe pre-existing patents, or may successfully compete with them, is not my province to determine; it is sufficient for this office that they present points of novelty, and for these letters patent have been granted.

One of these patents is for an improved mode of confining the cutter in its stock, which is effected by a conical screw instead of the ordinary device. Another is for improvements in various parts of an entire planing, tonguing, grooving, and beading machine, which cannot be understood without drawings and an elaborate description. Another feeds by endless belts of bars or slats, carried by rollers, and supported between the rollers by platforms on both sides of the board to be planed; and this apparatus is combined with a cutter whose shaft is placed diagonally to the board, and, with a gang of adjustable saws, to divide the board into strips of any desired width.

When the lumber to be planed is very thin, such as shingles, &c., great inconvenience is likely to arise from its vibrations during the operation, which render it impossible to give the surface the desired smoothness. To remedy this evil the cutters have been made to work through a plate, the sides of the opening being so levelled as to render it as small as possible. Upon this plate the shingle, &c., to be planed, is placed, and is of course pressed more uniformly and nearer to the point where the cutter is operating, than would be possible with the rollers which are ordinarily used.

I will notice but one other patent for improvements in planing. This improvement is intended for planing, or rather smoothing, surfaces which are irregular in one direction—to wit, longitudinally—such as the legs of piano fortes, which are polygonal in their cross section. The ordinary cutter is used with sliding boxes on each side of the block to be smoothed, and attached to the carriage is a guiding groove, through which the cutter shaft passes, and by which, as the carriage moves on, the cutter is raised or depressed, according to the shape which the block is to receive. The different sides of the block are successively turned to the cutter to bé smoothed.

Several patents have been granted within the year connected with boring, mortising, tenoning, and turning, but none of them present the strongly marked features of novelty which would entitle them to particular notice in this place. They are but slight modifications of previously existing machinery.

Barrel machinery.—The only patents granted this year connected with coopering, are for improvements upon various parts of an entire set of barrel machinery. Of these patents there are two, both of which are too complicated to be understood without drawings. These machines are calculated to operate well, but do not sufficiently differ from the machines already in use to exert any important influence upon the branch of manufactures with which they are connected, or to render a description of them in this place particularly important.

Lath machines.—Two patents have been granted within the year. Both of them seize and gripe the block while the knife is operating upon it, and release it when the knife is withdrawn, to allow the block to fall down before the knife, preparatory to another cut. This operation is effected by machinery, differing in one machine from that used in the other, both of which are patented. One of the machines has also an improved mode of clearing itself from splinters, and of delivering the laths in parcels of such numbers as may be desired.

Shingle machines.—But one patent has been granted within the year for improvements in machinery for cutting shingles, and that is adapted to cutting them of a peculiar form. The shingle cut by this machine does not taper from one extremity to the other, but the taper is confined to about half the length of it at one end, the faces of the remaining half being parallel to each other. This shape of the shingle avoids the bending which is incident to those of the ordinary form, when nailed upon the roof—an object well worthy of attainment. Patents have been heretofore granted for machines to cut the ordinary shingle, until the subject appears to be exhausted.

Splint machines.—The manufacture of friction matches has become so extensive in this country, and the necessity of offering them at a low price is so absolute, that any improvement which facilitates their manufacture is of very considerable importance. Machines for manufacturing the splints with great rapidity and economy have heretofore been patented; but after the splints are made, they are placed in a kind of a lattice work rack in considerable numbers, where they are held for the purpose of dipping. This requires considerable time and labor. To facilitate this operation, a machine has been invented and patented within the year for cutting the splints, and at the same time arranging them in the apparatus for dipping, so that no more time or labor is required than if the splint were made and dropped from the machine. To effect this, the block of which the splints are to be formed is carried against a tube cutter, whose tubes diverge a little and communicate at their outer ends with other diverging tubes, which again communicate with the openings in the dipping frame intended to receive the splints. As each successive splint is cut and passes into the tube cutter, it forces out the splint previously cut into the tube beyond, and thence in the same manner it is forced into the dipping frame, which advances as it is filled, presenting new openings for the splints as they are delivered from the machine. The machine manifests much ingenuity, and promises great usefulness.

FIRE-ARMS AND IMPLEMENTS OF WAR.

But two patents have been granted within the year for improvements in fire-arms, one of which is for an improvement of the "continual prime," and its application; and the other is for an improvement in the manufacture of wrought iron cannon. Both of these inventions are said to be of vast importance, and I therefore consider it my duty to call your particular attention to them.

"Continual prime" has long been in use, particularly in Europe. It consists of a small and very flexible tube filled with percussion powder, and flattened. A long strip of this is placed in some convenient cavity in the stock or lock of the gun, from which it is fed to the required point by any convenient device. The end of this prime is so situated that, as the cock descends upon the nipple, it cuts off a small portion of the prime, carries it down upon the nipple, and explodes it. As the percussion powder extends uninterruptedly through the whole of the strip of prime, the whole is sometimes exploded by being cut off, and sometimes by the explosion which takes place between the cock and the nipple. This renders the use of continual prime too unsafe for practical purposes, although it would otherwise be of great value. The improvement above alluded to is intended to obviate these inconveniences, and appears well calculated to attain the object at which it aims. The following extracts from the patent will give as clear an idea of the invention as can be presented without drawings:

"The nature of the first part of my invention consists in so making primers of fulminating mixtures, or such compounds as ignite by percussion, as to have a series of any number of primers in a continuous strip, but each separated from the others, to prevent the communication of fire from the one exploded to the others; by means of which, a magazine of such primers can be carried in connexion with the gun or other fire-arm, and each primer exploded without any danger of communicating the fire to the rest in the series.

"And the second part of my invention consists in connecting with all kinds of fire-arms, such as cannon, guns, pistols, &c., a magazine for containing primers, made in accordance with the first part of my invention, from which the primers may or can be fed forward to the place where they are to be cut off, preparatory to being exploded, or directly to the place of explosion; this magazine being so connected with the hammer or other moving part of the lock as to push forward the primer by the movement of the lock.

"The mode of making the series of primers, under the first part of my invention, which I prefer, is that represented in the accompanying drawings, and is as follows, viz: A strip of paper, either in a moist or dry state, is, by means of appropriate instruments and by the application of pressure, forced out into cup forms, the spaces between the cups being sufficient to prevent the communication of fire from one to the other. These cups are filled with the percussion or fulminating mixture, even with the original surface of the strip; it is then coated with a varnish of gum lac dissolved in alcohol, and covered with a thin strip of paper, and the whole is then varnished over, which renders it imperviable to moisture. It is important that the two strips of paper be made to adhere in the spaces between the several cups containing the fulminating compound, and that none of the mixture be deposited or left on the spaces or divisions. The method which I have pursued in making these primers is, to form the

cups in the paper by forcing in the mixture, the one operation being sufficient instead of two; and it will be evident that this can be done by placing the strip of paper on a bed, having a countersink of the form intended to be given to the cup, and laying the paper thereon, and the mixture forced into it by a piston working in a hole in a plate placed above the paper to keep it in place, and to hold the mixture and form a guide for the piston."

"What I claim as my invention, and distinguished from all other things before known, is, first making primers of fulminating mixtures or such compounds as ignite by percussion in a continuous series; each primer, or any two, or greater number, being separated from the others by a substance which is more or less combustible than the fulminating mixture, by which one or more may be exploded without communicating fire to the others.

"Secondly, the mode herein described of moving and measuring out the primers by the movement of the lock, substantially as described."

It will be perceived that the prime, from the peculiar shape given to it, is such, that machinery for feeding it can be made to operate upon it with great accuracy; and it is therefore the less important to describe the feeding apparatus, which would require drawings.

The subject of the second patent above mentioned will be clearly understood from the following extract:

"This improved cannon is formed of a series of rings or short hollow cylinders, of wrought iron or steel, or of wrought iron and steel combined, which rings are joined together by their ends in sufficient number to make the length required for the whole cannon. Each ring or cylinder is formed by winding or turning a piece of iron of the thickness required for the walls of the cannon round a mandril, and welding its ends together by a scarfed joint; or, second, several rings may be formed of thin iron, and of different sizes, so that one shall slip over the outside of another, until a sufficient thickness for the cannon shall be attained, when, by welding these several rings together, a single ring is obtained; or, thirdly, long bars of iron or steel of a width equal to the length of a ring, the ends being scarfed down, may be wound over a mandril or spindle, in the manner that pieces of riband are wound upon a block. These spirals being welded together, form a complete ring or hollow cylinder; or, fourth, long and narrow bars may be wound upon a mandril, side by side, and upon the top of each other, until sufficient length and thickness be attained for a ring; and these turns being welded together, the ring is formed.

"They are next to be heated and placed end to end, and welded together, and thus a hollow frustum of a cone is formed of a length required for the cannon. The trunnions are to be welded upon the sides of the cannon, either before the full length is made out, or when it is completed, or they are welded upon a separate ring or band larger than the cannon, and secured to the same by a screw, the thread of which is cut upon the outside of the cannon, to fit a corresponding thread cut upon the inside of the ring. The breech pin may be screwed into the cannon after the cannon is bored and turned, or it may be welded in previously to finishing the cannon.

"What I claim as my invention in the foregoing specification is this, viz: I have invented a new and improved kind of cannon, which is formed of a series of rings or short hollow cylinders, joined together by their ends,

in sufficient number to form the length required for the cannon; and for this I claim letters patent."

The process of the patentee differs but slightly from some of those previously resorted to, but his practical results may be widely different. The *principal* obstacle which has heretofore been met with in the manufacture of wrought iron guns has not consisted in the difficulty of forming or welding the parts of which the gun has been composed, but in welding these parts to the already partly formed gun—(and this part of the process does not appear to have been particularly improved.) For this purpose it is necessary, at each successive welding, to raise to a welding heat the large mass of iron to which the parts are to be joined. When the guns are comparatively small, they may bear this process without serious injury, and without great danger of imperfections in the welding; but when the gun is very large, the intensity of the heat required, and the readiness with which iron combines with oxygen, carbon, and other impurities to which it is necessarily exposed during the process, are such, that the iron becomes deteriorated, and a perfect weld is rendered a matter of extreme difficulty, if not impossibility.

In all ages, since the invention of cannon, attempts have been made to construct them of wrought iron; but when subjected to experiment, they have uniformly failed, and gone out of use. When they have been burst by powder, or otherwise broken, the fractures in their different parts have presented almost every variety—from tough, perfectly welded wrought iron, to the coarsest granular; and at many points the metal does not appear to have adhered at all. The features of the iron above mentioned may be found in fragments of the gun which recently burst on board the Princeton. Until some improvement in welding, not hitherto known or practised, shall have been discovered, to obviate the imperfections which now appear to be incident to it, it is to be hoped that no attempt to introduce very large guns of this kind will be successful.

Further remarks might be made upon this subject, which is at the present time one of vast importance; but I withhold them, as they would lead me beyond the proper limits of a report.

HYDRAULICS AND PNEUMATICS.

Since this class came under my charge, applications have been numerous; but they have generally been rejected for want of novelty, or are still pending. But one patent has been granted, which was for an improvement in the fire engine, which consists in so constructing the machine that one pair of its wheels, while the engine is in operation, may operate as fly wheels to equalize its action.

In looking over the list of patents granted within the last year, I find none of a miscellaneous character which require particular notice. Several have been granted not properly within any of the classes herein before reviewed, but they do not possess that degree or kind of novelty which would render them the subject of useful remarks.

In reviewing the patents for the year, it has been my object to call your attention to such, and such only, as indicated progress—to those which possessed important usefulness in themselves, or that peculiar and striking novelty which is calculated to render them a centre, around which future inventions will cluster. I have sought to show you not only that

the arts have progressed, but to trace out the important steps by which they have advanced.

If improvements deserving notice have been omitted, it has arisen from inadvertence; and if unimportant inventions have been rendered too prominent, I have erred in judgment. Enough, however, has been developed to show that inventive genius has not slept, but has steadily shed its cheering influence upon every department of the useful arts.

Some of my remarks may, perhaps, be regarded as strictures; but they were not written in unkindness, nor in a dictatorial spirit of self-sufficiency. They are presented with all diffidence, and with a sincere desire that some among the less informed class of inventors may derive advantage from their perusal. The learned I do not presume to instruct; and where I have erred, I shall rejoice in the discovery and correction of the error.

The duty assigned me is performed, and the results of my labors are respectfully submitted.

W. P. N. FITZGERALD,
Examiner of Patents.

Hon. Edmund Burke,
Commissioner of Patents.

January 21, 1846.

I.

Letter from Professor Morse, upon the magnetic telegraphs in operation in Europe.

NEW YORK, *February* 2, 1846.

DEAR SIR: In compliance with your request, that I would give you some facts in relation to my electro-magnetic telegraph illustrative of the difference between my system and other systems more recently established in Europe, I would say that, with a view of personally examining electric telegraphs in England and France, I made a rapid tour in those countries in the autumn of the last year. The electric telegraph most in use at present in Great Britain is that invented by Messrs. Cook and Wheatstone, the former of whom, it appears, had his attention first drawn to the subject at Vienna, in 1836, and Professor Wheatstone dates his own invention from the year 1837.

The electric telegraph upon the Paris and Rouen railroad is the joint production, I believe, of M. Foy and M. Brequet, and conceived and executed within the last two years.

To illustrate more perfectly the difference between my system of magnetic telegraphs and the two just mentioned, I will briefly describe the two European inventions. The principle of mine has been already described in a former report of the Commissioner of Patents, and it is, therefore, unnecessary to repeat the description of its machinery.

For the abbreviated description and plates of Wheatstone's rotating disc telegraph, invented by him in 1841, as an improvement on his former plans, I am indebted to my ingenious friend and assistant, Alfred Vail, esq.*

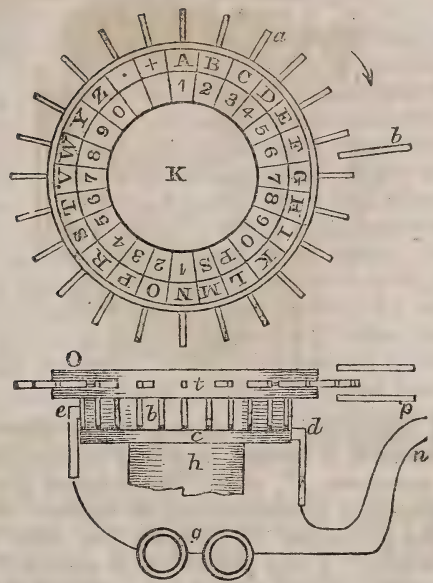
Professor Wheatstone invented his first telegraph in 1837. It was an improvement of Baron Shillings's *needle telegraph*, invented in 1833. The *deflection* of the *magnetic needle* is the basis of both. The *attractive power of the electro-magnet*, which is the basis of my printing telegraph invented in 1832, was used by Wheatstone in 1837, simply to release the detent of a common alarum to give notice to the attendant that a communication was about to be made. This magnet was made to act by a special circuit, by means of which a magnetic needle was deflected and closed a circuit with a local battery which charged the magnet. This is the only purpose for which the power of the electro-magnet was used in the telegraph by Professor Wheatstone, until the year 1841. There is no instance of any attempt to record or print characters by means of magnetism previous to my invention.

Wheatstone's Rotating Disc Telegraph, invented in 1841.

Fig. 1 represents that portion of the instrument which belongs to the *transmitting* station, of which K is a circular disc, with the alphabet and numerals marked in two concentric circles upon it; *a* are handles projecting from its rim, one to every letter, by means of which the disc is turned upon its axis, and brought to that position, *b*, required for signalizing a letter. O is a side view of the disc, K; *t* is the rim of the disc, with its holders; *h* is a portion of the axis of the disc, shown as broken off; *c* represents a

* They who are desirous of obtaining an account of most of the telegraphic plans, on the electric principle hitherto devised, will find Mr. Vail's larger work, entitled "*The American Electro-magnetic Telegraph*," a valuable addition to their library.

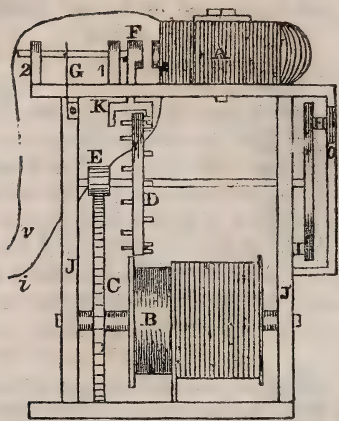
Fig. 1.



silver band surrounding a pulley or hub upon the axis, and directly behind the disc. Upon the hub are metallic ribs *b*, parallel with its axis, corresponding in number to the letters on the dial. Each rib forms a metallic contact with the silver band *c*, and are separated from each other by pieces of ivory fastened to the hub. Both the ribs and ivory pieces are made perfectly smooth and even upon their surface; *e* is a metallic spring, with a portion of it pressed against that portion of the hub between the silver band *c*, and the disc *t*, in a manner that when the disc is turned the metallic ribs and ivory pieces shall alternately come in contact with it. To this spring is soldered a wire connected with one pole of the battery *g*, and from the other pole proceeds the wire *n*: *d* is another metallic spring, similar to *e*, but pressing *only* upon the silver band, with which it is always in contact, and to which a wire, *p*, is soldered. Whenever the spring *e* is in contact with any of the metallic ribs, there is a continuous connexion from *n* to *p*, viz: from *p*, to the spring in contact with the silver band *c*, thence to the rib with which the spring *e* is in contact; then to the spring *e*; then to the battery *g*, and then to the wire *n*. If, however, the disc O should be turned, so that the spring *e* is in contact with the ivory, then the circuit is broken at that point; and in this manner the circuit is alternately broken and closed as the wheel O is turned from one letter to another, by means of the handles at *t*.

Fig. 2 represents a side elevation of the dial and clock work of the *receiving station*. A represents an edge view of the electro-magnet, from which proceed the two wires, *v* and *i*, which connect with the wires *n* and *p*, of figure 1. J and J is the brass frame containing the wheel work, C and E, the pin-wheel D, the dial plate I, and the barrel B, which is driven by a weight and cord. In the side of the wheel D are pins projecting from the rim, parallel with the axis, and are equal in number to the divisions, or letters, upon the dial I. They are, however, placed alternately on each side of the rim. F is the armature of the magnet,

Fig. 2.



fastened upon a horizontal rod, sliding freely through the standards, 1 and 2. G represents a spring, fastened to the frame J, and which carries back the armature, F, when the magnet has ceased to attract it. From the armature there extends downward an arm, K, which, as it approaches the pin-wheel D, presents two arms or pallets—one on each side of the wheel. These pallets are so arranged with regard to the pins, that if one pallet releases a pin on one side of the wheel, the same movement will cause the other pallet on the other side to arrest the motion of the wheel by its striking against the next alternate pin. H and I is an edge view of the circular dial, enclosed in a case, with a single opening at O; so that only one letter at a time can be seen. This dial, I, is in every respect marked as the disc in fig. 1.

Fig. 3.

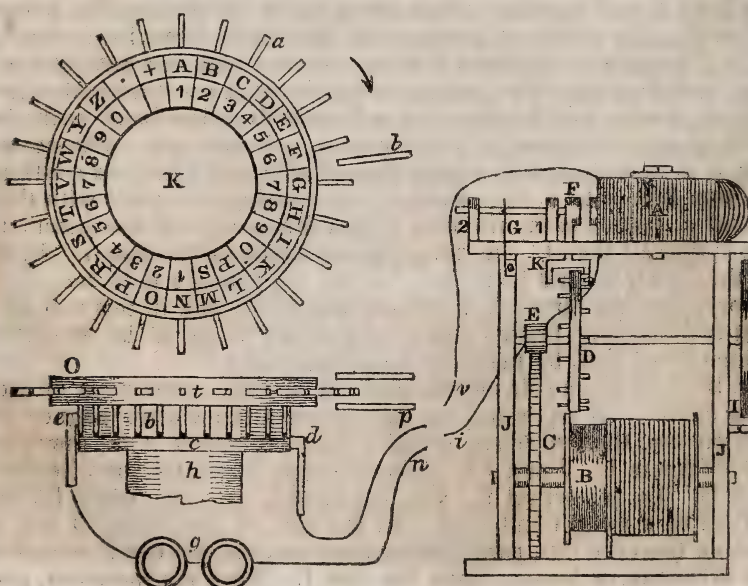


Fig. 3 represents the two instruments—O, the *transmitting* instrument, and the right hand figure the receiving instrument. The wires *v* and *i* are respectively connected with *p* and *n*. It will be observed that the armature F is not attracted, and that the right hand pallet is checking the pin-wheel, so that the dial is stationary. If, however, the disc *t* is turned so that the circuit is completed, by the contact of the spring *e* with one of the ribs, instantly the armature is attracted by the electro-magnet, which will carry the right hand pallet away from the pin-wheel, and which will then move by the action of the weight upon the barrel B, until it is checked by the left hand pallet, which had advanced to the wheel at the same time the other receded. This single operation has moved the disc one division, and the armature is still attracted. Now, let the disc *t* be turned until the spring *e* has been passed by the rib, and is in contact with the ivory only—instantly the current ceases; the armature F recedes from the magnet by the action of the spring G; this has taken the left hand pallet from the pin-wheel, which is permitted to move until the next pin strikes against the right hand pallet. This has now brought another letter in front of the aperture at H. Thus, it will be seen that the design of this instrument is to bring into view, at the aperture, such letters as are required in transmitting a message.

Suppose letter A is at the point *b* of the *disc*, and letter A of the *dial* is opposite the opening. The instrument is now ready to transmit; and let the letter I be the first of the message. The operator gently turns the disc round in the direction of the arrow, so that each time the circuit is broken a new letter appears at the dial, and each time it is closed by the operation of the pallets, in checking and releasing the pin-wheel.

This is its operation until the letter I has reached the point *b*, when a short pause is made. The next letter, H, requires but one movement of the disc, then follows A, then V, then E.

In relation to this instrument, Professor Daniell says: "We can only further briefly allude to two of the most important modifications of this invention, which Professor Wheatstone has made for specific purposes. By substituting for the paper disc, on the circumference of which the letters are printed, a thin disc of brass, cut from the circumference to the centre so as to form 24 springs, on the extremities of which types or punches are placed, and adding a mechanism, the detent of which, acted on by an electro-magnet, causes a hammer to strike the punch against a cylinder, round which are rolled alternately several sheets of white paper and of the blackened paper used in the manifold writing apparatus, he has been enabled to obtain, without presenting any resistance to the type wheel, several distinct printed copies at the same time, of the message transmitted."*

This invention of Professor Wheatstone I critically examined in September and November last, (1845,) at the Nine Elms and at the Paddington station, London, and also at Amsterdam, in October. At Paddington, I gave a name of 19 letters to be transmitted, and requested specially that it should be sent and returned as speedily as possible, as I wished to test the number of letters that could be shown in a minute. The result was, that the name (after several failures to spell it right, and giving sometimes the letter before and sometimes the letter after the true letter in the alpha-

---

* Daniell's Introduction to Chemical Philosophy, page 580, 2d edition: London, 1843.

betic arrangement in the disc) was completed in one minute and a quarter. I inquired how many could be shown in a minute, and learned that ordinarily 15 or 16 letters, although 20, and even 24, had been recognised. This rate was corroborated at the Amsterdam station of the Harlaem and Amsterdam line, on which Wheatstone's disc telegraph is used. 15 or 16 letters per minute was the usual rate of transmission; but I found here, as at Paddington, that the disc did not rotate with correctness; often giving the wrong letter, so that the word was generally guessed at, and frequently required repetition. In this arrangement it will be observed that Professor Wheatstone uses but one circuit.

In Paris, in the latter part of October and beginning of November, 1845, I examined the telegraphic system in operation upon the experimental line, made by order of the government between Paris and Rouen, a distance of 85 miles. This system is an ingenious application of a rachet-wheel escapement, acted upon by an electro-magnet, to the movement of two arms, imitating the configurations of the aerial telegraph already in use in France.

The following is a concise description:

Fig. 1

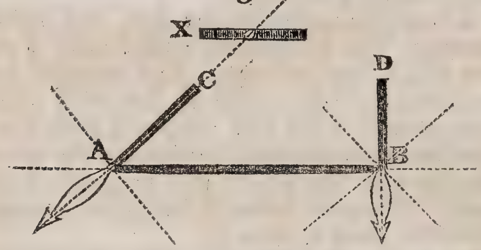

Fig. 1 represents the face of the telegraphic instrument; A B is a fixed dark line upon the face or dial plate; X is an arm having one motion on its centre in the direction of the dots; A C and B D are movable arms, turning on the pivots A and B respectively. The dotted lines are the various positions which each arm can assume, making, by their combined movements, 128 different configurations. The hand X, when horizontal, indicates that the sign is to be read horizontally; when inclined in the direction of the dots, the sign is to be read perpendicularly. This telegraph is operated by two circuits, one for the movement of each arm, the axles of which pass through the pivots A and B respectively; behind the dial and upon this axle is a rachet or escapement wheel of 8 cogs. The cogs of this wheel, connected with a clock train of wheels, are released by the power of the electro-magnet operating upon a lever. At every release of a cog, by the action of the magnet the arm takes a new position, assuming for an instant each intermediate position until it comes to the one desired, when it stops. A single connexion and break of the circuit releases one cog.

With this arrangement M. Brequet states that 10 configurations or signs can be given in a minute. In a note, however, from Mr. Fox, the accomplished administrator of the telegraphs of France, he informs that 28 have been given in a minute; but ordinarily it can only give 10 or 12, and *this* (it will be perceived) requires 2 circuits; consequently it gives at the

rate of 6 signs ordinarily, or at the utmost 14 per minute, for a single circuit.

It will be sufficient to state that by my system I give, with a single circuit, at least 60 characters in a minute; not merely shown temporarily, but recorded in a permanent manner upon paper, to be read at any time.

The efficiency of the three systems will stand thus represented in figures:

The American system, 60 per minute;
The English system, 15 per minute;
The French system, 6, or at most 14 per minute;

with the advantages in favor of the American, that the characters are made permanent and the operation of the instrument surer, the simplicity of the machinery rendering it less liable to be deranged by atmospheric changes or other accidents.

With sincere respect, sir, your most obedient servant,

SAML. F. B. MORSE.

Hon. Mr. Burke,
Commissioner of Patents, &c.

REMARKS ON THE TABULAR ESTIMATE.

In presenting the foregoing tabular estimate, it may be proper, in order to prevent mistake, to repeat what has been stated in the former reports of this office—that no claim is laid to complete accuracy. All that has been attempted has been merely to furnish an approximation, which, although in particulars sometimes rising above, and at others falling short of the actual state of the crops, might still serve, in general, for want of better materials, the purpose of comparison, and form some basis for calculations, in gross, respecting the agricultural resources of our country. To hope to accomplish anything beyond this, with the means at command at present, would be a vain undertaking. Yet it is believed that the grounds on which the estimate is made, with a readiness at all times to correct errors, and an increasing preparation of experience in the use of the materials, will aid essentially in giving more reliable accuracy. Those who will candidly review the history of the crops, as it has been collated from notices made on the spot, and mark the causes at work to affect them, it is presumed will admit, for the most part, the justness of our conclusions; and to such it is unnecessary to state the extreme difficulty of arriving at an estimate which will satisfy those who choose some easier method of decision. Various methods have been proposed for reaching the desired object; but, in the absence of an actual census, no better mode than the employment of similar data, yet more extensively gathered and perfected by comparisons, appears to us practicable.

Some writers in the public journals seem to place great reliance on the amount of wheat brought to the Atlantic ports, and claim that this is the truest test of the increase or decrease of the crop. While we admit that this is an important element of computation, and as such is ever regarded in our estimate, it is doubted, however, if this alone is sufficient. The comparative decrease or increase of the other crops in the place where such product is raised, may often exercise an important influence to modify such a calculation. If one product, on which reliance has been placed for feeding the stock, has been cut off, resort must be had to another; and the degree of such consumption may thus very essentially vary the surplus left for the market; so that, though the amount of wheat raised in the western States may be actually greater or less, as the case may be, the amount brought to the Atlantic ports may be less or greater, according to a variety of other circumstances irrespective of production. The demand in the way of trade, therefore, is only one of the many things to be considered. The greater previous stock remaining; the greater ease of placing the surplus of any year in market; the kind of payment received; the ease and expense of preparation for use at any given period, with a variety of other circumstances, must tend not a little to modify the amount received at the nearest place of exit, or at the remoter markets. So that the amount passing any lines of transportation, or entered at any office, will not by itself give the correct data for an approximation to an accurate estimate.

In using the various elements on which estimates are made, reference must likewise be had to the ability, from experience or means of observation, of the informant, his freedom from bias, and the absence or presence of extraneous causes which may operate to influence his judgment. It is obvious, therefore, that it is no easy matter to sift out and discriminate the true from the false, and thus form, by a series of deductions, a result which may have

some pretensions to be regarded as founded on correct principles of judgment. Such means, however, as are within our reach, have been resorted to, and, with all necessary deductions, they have been employed to secure, as far as practicable, a candid view of the whole state of the case.

The amount of materials collected during the past year exceeds that of any former year; though we still have to regret, that, on account of no answers to some of the circulars for information, the means for estimate in some sections is less complete than it might otherwise have been. A greater number of the public journals and agricultural papers, both at home and abroad, have been carefully examined, and such information as they contained collated and arranged in such a manner as to form a history of the crops through the season. The advantage of this plan is apparent, as it enables any one to judge, from one period to another, of the causes influencing the staple crops of the country, and affords, in some degree, a criterion by which to arrive at the more correct conclusion as to the amount raised.

In consequence of a census of population in four States, we have been enabled to correct our table of estimated population. These are New York, Michigan, Illinois, and Georgia. In New York, directions were likewise given to the marshals to collect the amount of the principal crops raised during the preceding year. These statistics have been procured from the office of the secretary of the State of New York, and have been made the basis of our estimate for the year 1845. The same has been done, so far as any such data could be obtained, in the case of the other States.

The disinclination of many to communicate the amount of the products of their industry on such occasions, induces a belief that such an estimate will oftener be found to fall below than to exceed the actual amount of the crops so raised. Allowing this cause to operate to some degree, it would tend to approximate our former estimate considerably nearer to the statistics reported on such official authority.

In most cases it has been deemed advisable to give only the round numbers, leaving the fractional parts. This cause sufficiently shows the comparative product, and is as likely as any other to be accurate.

The progress of agricultural knowledge is steadily onward. States are turning with deeper interest to providing means for encouraging the farmers and planters in their respective limits; surveys of the soil and various products are set on foot; and thus, much valuable information is elicited. Men of science are devoting themselves to the illustration of the principles of agriculture, as a science founded on careful experiment. New journals are every year established, and numerous volumes published, designed to convey to the husbandman, planter, and grazier, the orchardist and the dairyman, the results of investigations at home and abroad. Agricultural societies and farmers' clubs are greatly on the increase; and the numbers who attend their exhibitions, and take a part in their deliberations, shows the deeper interest which is every where awakened in securing the benefit of these auxiliaries, to the correct and profitable arrangement and development of the agricultural industry of the country.

Some advances are likewise making towards the introduction of this science as a subject of common school education and instruction in primary schools, as well as in the establishing of institutions more expressly designed for this particular purpose. No subject is receiving more earnest attention, in all the various periodicals and volumes adapted to the

agricultural class, than is that of manures; and the applications of chemical and geological science to this object are daily becoming more important and useful.

New enterprise, too, has recently been directed towards the improvement of stock, by the importation and crossing of breeds, and particular care to note their adaptation to the different sections of the country.

Every year introduces, likewise, to the agriculturist, some additional implement by which his labor is lessened, or better done; and, while he is thus saved somewhat of the sweat of his brow, he is likewise assured of greater profit from the fruits of his industry. There is, thus, mutual dependence as to the pursuits of the farmer and those of the artisan. Mechanical industry presents him with the results of her inventive genius. With these in hand he forces from the earth her increase, and, by the blessing of a kind Providence, is enabled to pour out to the community around him a lavish of nature's bounties, such as no other country can so universally boast. In view of his own improved tools and means of culture, he may well wonder how his fathers, and even himself, formerly, could have been satisfied with the ruder ones which have been so long in use. We are, however, but at the commencement of these better things.

The researches of each successive year, and the multiplied facilities added to the train of conveniences enjoyed, authorize the belief that the advancement of agricultural industry is destined far to exceed any that has yet been seen.

There is no want of adaptation of soil, or of fertility, or of means of industry, or of bone and sinew of free yeomanry, who may enjoy the fruits of their own labor; and, as an increasing population spreads far and wide over the whole face of the land, its abundance, under the smiles of Heaven, will ever suffice for both the native born and for the emigrant, who, from foreign shores, seeks an asylum from the oppression which starves him and grinds him to the dust.

Even the evils which attend the greater or less failure of some important crop, as in the present year has, to some extent, been the case with the potato crop, are not without their good effects; insomuch as they will call forth scientific investigation, observation, and practical industry, to determine and apply the remedy, and thus often throw new light on the true theory of germination or progress. More care will probably be taken in selecting seed, in cultivating the soil, and in storing the crop; new varieties may be secured; and the still greater failures, which might otherwise have taken place, thus be prevented. Some of these observations, in general, will receive yet fuller illustration in the future consideration of the specific crops as they come under our review.

We are not, too, without our resources even in the case of the more permanent unproductiveness of some particular crop. The history of our country, and the wide extent and variety of soil and climate, enable us to turn our attention from one thus failing to another, and in many cases new products may thus become introduced and acclimated among us. To any one who may live a half century hence, the comparison in this respect may be a striking one. Fields blooming with some plant now scarcely known may then frequently meet the eye, and afford promise of a rich harvest to repay the enterprise and skill devoted to its culture; and the octogenarian of those days may possibly find, but few and far between,

the patches of some fruit of the earth, which he was wont in his boyhood to see, frequently wide spread over his native soil.

As commerce and enterprise open to us the vast empire of China, and the interior of South America, it would not be surprising if there should be discovered there products well adapted to sections of our own country, but which are as yet unknown among us. It should, therefore, be an object to keep a lookout for every thing which may tend to benefit the agricultural industry of our country; and even if the boon is gained by the price of numerous fruitless experiments, yet success may often reward diligence and patient effort to accomplish the end.

By a reference to the report of the Commissioner of Public Lands, we learn that 1,754,763 acres have been sold during the past year. Now, although we can by no means assume that all of this, or even the greater portion of it, goes under cultivation at once, it still must be supposed that a part of it must add to the amount devoted to agricultural supply in the States where it is located; and this item deserves notice in forming our estimate of its products.

The same may be said with respect to the amount of increased population from emigration. The number of emigrants from Great Britain and European countries generally, to the United States, is believed to have been greater during the past year than in the previous one, when it amounted to from 80 to 100,000; a portion of these, no doubt, engage in agricultural pursuits, and thus have some influence, not only on the consumption, but also the production of the crops.

THE SEASON.

Some persons reading the former reports may have thought the few pages devoted to extracts from the various public journals relating to the weather is of little or no use; but we do not thus view the matter. On the contrary, we believe that there are advantages in taking even the partial information just as it is given, and presenting it to the public from year to year, that they may judge of the variations to which the different crops are subjected, and the consequences which have thus resulted. We have therefore watched with increased attention the indications of the season, as noticed in the public papers. These, though in most respects too defective for any extended generalization, yet aid somewhat in the conclusions formed respecting the crops.

It is obvious that a favorable planting season, or the state of the soil, as previously affected by the various changes of the weather, must have some influence on the productiveness of the crop, allowing the usual season of growth to have been enjoyed. Every year exhibits greater or less degrees of cold or heat in the various sections of our vast country; and ranging, as it does, from latitude 25° to 49° N., not including Oregon, which reaches to 54° 40′, embracing seaboard and inland, mountain and plain—intersected by numerous rivers, and overspread in many parts with forests in all their native wildness and vastness of growth—the diversities of season must, of necessity, be numerous, and their effects deserve serious consideration. As the seed time or growing period, or harvest, must vary by weeks, and in some cases months, it is obvious that, were there a general prevalence of some particular temperature or accidents of climate, the effect will often be found to be different, if not wholly opposite, even

in the several sections where such a cause exists. The same remark applies to the nature of the crops. A season highly favorable to one kind of production may be injurious to another. The same extended rain which is needed, and therefore highly beneficial, in one part of the country, may be less adapted to another in a different condition, in relation to the similar or diverse crop, as the case may be. The weather, for instance—to take up the subject in a somewhat different point of view—which may be most suitable at some period to a young growth of cane or of cotton, may be unfavorable to another kind of crop, as that of corn or of potatoes.

The season of sowing or planting, from one extreme point to another, probably reaches over two months or ten weeks. A rain, therefore, which might benefit a crop already in the ground, or injure it, might exert a very disastrous or favorable influence on some other, according to the previous condition in preparing the soil for the seed of some other product yet to be deposited therein.

We have gathered a large collection of notices respecting both the cold and heat, from April and on, in various parts of the country; of course, we shall have room for but a few quotations; but it is evident that there have been unusual variations of temperature during the past season. Late frosts are spoken of in the early part of the season—even in the southern sections of our country, where they are less to be expected than in the northern States. In connexion with these, also, we meet with very frequent complaints and lamentations on account of the want of rain.

In the month of April the drought is stated to have been unusually severe in some of the southern States. This seems to have been peculiarly the case in South Carolina and Georgia. Thus the Winyah Observer remarks: "The season continues very inauspicious for the planters in this neighborhood. April is rapidly passing away, without having given the showers common to the month. The tributary streams continue low, and the river is salt up to town. Several planters are using brackish or salt water to get up the rice crop; and those who plant in open trenches, without covering, are annoyed by the May birds. The corn and potato crops are suffering from the general drought."

Again: the Greenville Mountaineer, of April 25th, has the following notice:

"*Continued drought.*—Another week has passed without sufficient rain to lay the dust. The wheat and oat crops are very much injured, and in some fields entirely cut off. The corn and cotton seed that has been planted in many places cannot come up. The drought seems to extend throughout the whole United States, with the exception of light and partial showers in some sections."

Again: we learn from the Savannah Republican of April 30th, that "in Madison, Georgia, no rain of any consequence has fallen in four weeks. With the exception of one or two very slight showers, the deprivation at Savannah has been longer. Many of the planters are a month behind their prospects of last year at this period."

The Savannah Sentinel, in the early part of May, says: "We do not recollect ever to have seen so dry a spring as this has been. We have not had any rain of consequence since the 3d of February last; and the month of April, so famous for rain, has passed off with only five slight

showers during the whole month. The consequence of this drought has been serious injury to vegetation of every description in this section."

And, in the same public journal, about the same time, we find the following statement:

"*The drought.*—The almost unprecedented drought here, at this season, has extended far and wide, though we hope soon to terminate, as heavy rains (mostly with hail) have fallen recently in isolated places."

The Little Georgian (Forsyth) of the 2d instant says: "We have never witnessed a drought so extensive or so long in duration as the present at this season of the year. In a recent jaunt of some 130 miles, we saw only three districts, of very small extent, where there had been a rain in less than six or seven weeks. Wheat and oats, previously unpromising, are in many places almost entirely ruined, and vegetation of all kinds suffers severely."

Under the date of Macon, Georgia, May 5, it is said: "The severe and destructive drought still continues, enhancing the value of small grain and destroying the prospect for a cotton crop. Much of the cotton seed planted remains in the ground, without a possibility of vegetating until we have rain. The prospect for the season is by far the worst I have ever seen. Many of the young plants have withered from heat; and if this state of things continues ten days longer, every paper from Georgia to Memphis, Tennessee, will be heralding forth short crops."

Similar complaints are observed from St. Augustine, under date of 6th of May: "We want rain. Our corn and tobacco crops are suffering severely."

Drought, too, was experienced in Virginia early in the spring.

The Lynchburg Virginian has the following paragraph, about 20th of April:

"*The season.*—It has been now upwards of five weeks since we have had rain enough to wet the surface of the earth; a most extraordinary (and the 'oldest inhabitant' thinks unprecedented) circumstance, in this proverbially 'showery' month. During almost the entire period, too, the weather has been cool, and sometimes wintry cold. The consequence has been the entire loss of every variety of fruit, and extensive injury to the tobacco plants and to the early wheat, much of the latter being apparently destroyed."

Nor was this drought confined to these States. In other sections of the country we notice similar statements, in some instances coupled with complaints of cold and frosts. Thus, the Syracuse Journal of May 14th, in the interior of the State of New York, has the following notice:

"*The weather.*—Since the showers of the 25th ult. we have been entirely without rain until yesterday, when there was a refreshing sprinkling, and the appearance of more to follow as we were going to press.

"The drought has had an unfavorable effect upon vegetation, though a soaking rain would doubtless start every thing forward again like magic."

Again: the Wheeling Times, under date of April, says:

"The weather continues dry, with no appearance of rain. It also continues cold, especially at night. We learn that there is danger of the wheat crop, especially on the hills. The ground is too hard to work."

So, in Missouri, there is mention of great want of rain during April and the early part of May.

The Paris (Missouri) Mercury of 19th May says:

"Never have we seen here so gloomy a prospect for an abundant crop. There has not been rain enough to lay the dust for a month. Seed which has been put in the ground cannot vegetate, unless it should rain.

"Wheat is dry to its roots. We hear complaints relative to tobacco plants to pitch a crop, and fears are entertained on this subject. We would advise farmers to sow tobacco seed again, although late in the season."

The cold and frosts also were unusually late in the spring and the opening summer, and frequent notices have been gathered expressing apprehensions from this cause.

Snow is mentioned about the middle of May in Maine; in Boston, Providence, Greenfield, and other places in New England, we find statements of severe cold, frosts, ice, &c., which injured the fruit and vegetables in May, and even in June. The same was the case in the State of New York.

We quote a few notices as specimens of numerous others which might be mentioned:

"*The late frosts.*—The recent frosts have been very destructive to apples and peaches in several counties in western New York. The corn crop is not far enough advanced to be much injured by this untimely freezing. The weather is still cold, (May 20th;) anything but favorable to summer crops. Wheat generally looks well."

"There was a heavy frost on Wednesday, Thursday, and Friday nights, which did serious damage to nearly all sorts of vegetation in this region. Fruit, to a great extent, is destroyed; corn and potatoes were nipped to the surface of the ground; while beans, pumpkins, cucumbers, and many vegetables, were completely killed. Snow fell on Friday."—*Le Roy Gazette, June* 4.

"There was a severe frost in this vicinity on Thursday night last, which effectually 'used up' corn, beans, tomatoes, and almost everything else which frost could affect; gardens are almost entirely destroyed."—*Livingston Republican, June* 3.

"We had a frost on Thursday night last that used up everything in the fruit line that had previously escaped."—*Cattaraugus Whig, June* 3.

"Further damage was done to the gardens in this vicinity by the severe frost of Thursday and Friday nights. All kinds of vines, and some varieties of garden vegetables, that were not protected, were greatly injured or entirely destroyed. Corn is almost cut down, but it is thought it will put forth again if the weather should prove favorable. Wheat looks tolerably well, but we judge there will be less than an average crop in this quarter."—*Ontario Repository, June* 4.

"One or two nights of last week this village and vicinity were visited by a severe frost; corn is materially injured, and fruit of all kinds is pretty generally killed."—*Batavia Advertiser, June* 3.

"We can scarcely recollect a season when the changes have been so sudden and remarkable. On Thursday night of last week ice was made of the thickness of almost half an inch, and so cold was it that the ground was even frozen. Fruit is entirely cut off in this section, and we learn that the frost reached a good distance north and west."—*Cortland Whig, June* 5.

"We had several snapping frosts last week, the effects of which, we fear, will be felt upon the fruit."—*St. Lawrence Republican, June* 3.

A public journal in New Jersey, during the month of May, has the following: "The farmers complain most vehemently of the cold and backward spring. We have heard those experienced among them declare that they remember nothing like it during the last fifteen or twenty years. What is the philosophical reason?"—*Rahway Republican.*

In the early part of June, also, we find the following statements in different papers quoted from others, to which they are credited:

"The cold weather and frost of last week have nearly cut off the pea crop in New Jersey. The potatoes in the neighborhood of Germantown have also suffered greatly."—*Philadelphia Gazette.*

"We have just had three severe frosts. The wheat appears to be in full bloom. No doubt the bloom is killed by the frost, and that the heads will be deprived of germination. Therefore, what we call in this country the wheat heads will be dropped. More than half will be destroyed should the germination be stopped on what is now in bloom."—*Baltimore Patriot.*

"*Ice.*—There was ice made upon the edges of the ponds and ditches in the vicinity of Wilmington, Delaware, on Saturday morning last. It is supposed the tender vines would be destroyed by this cold; the corn, too, has suffered, but the grain will recover."—*N. Y. Express.*

In Alabama, in the latter part of April, there are similar complaints respecting the cold, backward season, and even frost. Thus the Montgomery Advertiser says:

"*The season.*—During the present week we have had a return of cold weather, with slight frost, which, in connexion with the previous spell of cold, will retard the season considerably. How the fruit generally may be affected we can hardly say, though we think, where it has been exposed to the influence of northwest winds, unsheltered by woods or houses, that it will be considerably affected in quantity, at least, if not in quality. The cold nights of this week must have checked the cotton, if not otherwise injured it, in low, moist situations, and will make the season somewhat later than that of last year."

From a large number of similar notices respecting the frosts and cold in the latter part of spring, at the west, we give only the following for the month of May, or June:

"*The weather in Cincinnati.*—We have had very cool winds and frosts for several nights past. The storms west of us, we suppose, have caused this change. Fires in the evening are not uncomfortable, and most persons are still winter clad. We are informed that on the hills north of the city on Wednesday night the frost was very severe, and that it destroyed many of the garden vegetables. Peas escaped; the tomatoes uncovered are swept."

[From the Cincinnati Gazette of 6th June.

We learn from a friend who has just crossed the State from Toledo to this city, that the appearance of the country north of the national road, and in some instances this side of it, is desolate in the extreme. What the long drought had left of vegetation, recent frosts have taken off. All that has appeared in the newspapers, within two or three weeks, concerning the destruction of crops, he saw verified. At Toledo, on Thursday night last, ice froze to the thickness of three-eighths of an inch."

Cold weather.—The State Journal at Columbus, Ohio, says: "The

weather has been unusually cold for the month of May, in this section of country. On Monday night and last night, (Wednesday,) the 5th and 7th instant, sharp frosts were experienced. Ice was formed at night, and stood until after sunrise on Tuesday and Thursday mornings. The tender vegetables are mostly destroyed. The corn has been nipped, and will be thrown back."

The Cincinnati Gazette of 4th June, speaking of the severe frosts of the latter part of May, says: "At Toledo, on the 29th of May, ice froze to the thickness of three-eighths of an inch, and the appearance of the country north of the national road is represented as desolate in the extreme."

"*Severe frosts.*—On Wednesday night last, May 7, our country was visited by a severe frost—so much so, that most all of the early vegetation was nipped to the ground. The early cornfields will be retarded at least three weeks; potato tops have been cut off, and serious apprehensions are entertained for the balance of the fruit crop—peaches, apples, grapes, &c."—*Terre Haute (Indiana) Express, May* 14.

"We had severe frost on Wednesday night last, which completely destroyed everything in the gardens that could be affected, and cut down the early corn in the fields."—*Connellsville (Indiana) Telegraph, May* 9.

"*Frost.*—Very serious injury was done to the gardens in this neighborhood by frost on Thursday night. The corn was also touched, but not so seriously that it may not recover from it."—*St. Louis Republican, May* 17.

The public journals during the months of June, July, and August, in very many sections of the country, were filled with lamentations on account of the distressing drought which prevailed. The heat rose to very high degrees in the thermometer. Thus, in the agricultural report for July, in the vicinity of New York, it is stated: "The month of July has been one of the dryest we have ever known. The earth has been so parched up that not only vegetation has suffered seriously, but even the trees show a want of moisture." And, speaking of August, it is said:

"The earth was parched to such a degree that there were great fears that every description of vegetation would be destroyed." So, in an Albany paper: "The drought is intense; the fields are almost baked with the heat, and the failing of springs and wells gives evidence how deeply the heat has struck in the ground. A few days more of burning weather will ruin the corn past recovery."

Partial showers relieved parts of the State, while others still continued to suffer from the great severity of the drought through the month of August. Thus, a public journal at Hudson says:

"While we have gratifying accounts of plentiful rains around us in almost every direction, we are still without any except a slight shower or so, and we understand that the same is the case in Dutchess and a portion of Ulster counties. The season throughout the whole country has been a remarkably dry one; but we believe no part has suffered to the same extent that we have here. Vegetation of almost every species is literally burnt up. A speedy rain might save our turnips and late sown buckwheat; but the corn, hay, oats, potatoes, &c., are little better than nothing. Again: A gentleman who left Syracuse on Thursday morning says there had been very little rain there for more than a month. Vege-

tation was suffering." Still further to the west in this State the same accounts meet us, thus:

"BUFFALO, *August* 1, 1845.

"The dry weather, which promised so much injury in June, has amply fulfilled all its promises. July has been one of the hottest and dryest months on record. The highest range of the thermometer was 104° in the shade on the north side of our farm-house in the country at 1 o'clock, p. m. The hot Sunday it marked only 98°. The Wednesday following, at the same hour, and in the same place, it marked 104°. The ground is literally dried up. The streams and springs have been lower in this month than I have seen them before since I have been a resident of this region, and that is some thirty-five years. The pastures looked as arid as a desert, and wherever fire was set, it run over them as over a stubble. It has been a very gloomy month for the farmers. All kinds of crops have suffered, but some more than others."

The same was the case in Pennsylvania and Maryland. We might quote pages of notices of the drought from June to August in the south.

The following are some of the statements which were made in the public journals in Virginia and the southern States:

The Washington Union says, in the month of July—

"*The drought.*—There has been a general complaint about the late oppressive hot spell of weather. Every one seems to think that it has reached the superlative degree; and whether he was in the city or the country, the south or the north, that it was the hottest spell he had ever experienced. To-day, however, we had a cooler and much more agreeable temperature. The excessive heat has been accompanied with an oppressive drought, which has withered the grass of our squares, and has been most lamentably felt throughout the country. The last Richmond Enquirer, speaking of the great tobacco growing county of Halifax, says: 'Much gloom hangs over that region of country in consequence of the crops being blasted by the scorching sun and alarming drought. Indeed, in every quarter, we hear melancholy complaints of the want of rain.'

"A farmer in Goochland told us that he had to send so far to mill that he thought he should send to Richmond, forty miles off, to supply his farm with meal; and, in North Carolina, we observe they send ninety miles, to Petersburg, to get their meal. We fear much distress and sickness will follow this extraordinary drought. On Saturday and Sunday we were tantalized by a prospect of showers, but in vain. Yesterday the heat was oppressive as ever, though we are glad to have to record no death from the immediate action of the sun, which, in the north, according to the papers from that section, has carried off so many suddenly to the grave."

The Lynchburg Virginian says, that of universality as well as duration the drought is almost unprecedented in the memory of the present generation.

A letter from Charlotte, N. C., of 5th July, says the earth has not been thoroughly wet since 3d February, and there had been no rain there for seven weeks.

The Charleston Courier thus quotes a letter of the 14th of June, from Fairfield district—

"Over my parched and naked fields drought has reigned, and does reign, supreme. My once verdant fields of small grain have withered and

died under the ravages of the chinch bug; my dwarfish and sickly corn is threatened with annihilation from the same cause; my pastures are ash-beds; my water courses sand beds, and my cotton barely rears its puny head above the scorched earth. When employed at my business, devastated oat fields, blighted corn, and stinted cotton, sicken my heart. When I stroll to uncultivated fields, famished hogs and staggering cattle are my comforters. Clouds pass over, thunder rolls, but all ends in mockery. Hope has been deferred till I have lost all acquaintance with it. It would seem inevitable that I must not only fail to make my bread, but that the whole country around must share my fate."

And in July, the Anderson Gazette, published in the same State, says—"This has been, thus far, the most remarkable season we ever knew; in many parts of this district the ground has not been wet since March, and the cherished hopes of many farmers are almost entirely blasted."

The Pendleton Messenger makes similar complaint; and, indeed, from almost every district of that State we hear of a most extensive and alarming drought. Again:

"*Dry weather.*—We have been informed that copious showers have recently fallen in some sections of the district; but, in this neighborhood, and throughout the country generally, the drought has continued, and the temperature has been that of summer heat. The crops in the fields and gardens have suffered considerably. We have not had any rain of consequence since the 13th of March last."—*Edgefield (S. C.) Advertiser, August.*

The same state of things prevailed in Georgia, as the following notices abundantly testify:

"*Great drought.*—Rain is wanted far and wide in this region of country. The Milledgeville Recorder says: 'We are greatly suffering for want of rain. And where are they not? It seems to us, from all we can see, that the whole country is parched. Dry as we are here, we understand we are not in as bad condition in this respect as other regions are, and this extending very much through Carolina, Alabama, &c. The Oconee, at this point, is said by our old citizens to be lower than it has been for the last forty years.'"—*Savannah Georgian, June* 12.

"*The weather.*—From almost every direction we hear complaints of dry weather and intense heat, and we regret to add that Athens is not an exception to the general rule. In nearly all this region, the crops are suffering for want of rain. During the last week the weather has been hotter than we have known it for years. The thermometer has reached ninety degrees for several days in succession, and once or twice has been up to ninety-four."—*Athens (Ga.) Banner, 24th June.*

"*Remarkable drought in Georgia.*—In Upson, Crawford, Pike, Monroe, Butts, Henry, and Fayette, no rain of consequence has fallen since early in March; and we have been assured by gentlemen from these counties that in no part of the State, since 1818, has any drought been more blasting, or prospect of the corn crop worse, than at present in these counties."—*Macon Telegraph, July.*

The weather.—The Fort Gaines Whig of the 7th June, says: "The drought still continues, with the exception of a few slight showers, scarcely sufficient to moisten the parched earth. No rain has fallen in this neighborhood since the middle of March. We are informed by planters that the corn crop is much injured, and will fail entirely if the drought

endures much longer. In many places it is but from knee to breast high, and already in tassel and silk. The Chattahoochee is lower than it has been known to be for many years. The steamboat Columbus, however, with great difficulty, and much to our surprise, reached here on Tuesday last from below, stored her freight, and returned to the bay."

In Alabama and Florida, also, the same complaints are numerous.

The drought in Alabama.—The Montgomery Advertiser of the 4th July says: "One of the severest droughts which has ever been experienced now prevails in this section of Alabama. On very many plantations the corn crop is nearly destroyed. Rain even now cannot restore it. Cotton in many places is seriously injured; and, unless we have rain soon, a short crop may be expected. As to gardens, especially in this vicinity, most of them are entirely burnt up.

"In Alabama, too, the drought extensively prevails. The Cahawba Gazette, July 2, says: 'A general drought seems to pervade the whole country. The corn crop is a total loss in many places—rain cannot save it.' The Marion Review states that 'vegetation is withered—dried; literally dried, like hay. We have not had, in many places, rain enough to wet the ground since the 1st of May.'"

The drought in Florida.—The Tallahassee Star of the 13th of June says: "This whole region of country is, at present, suffering under one of the most severe and distressing droughts which have been experienced in this climate for many years. Most of our springs, branches, and creeks have failed, and many of the old wells, which have hitherto borne a good character, have suddenly flanked out. Our different kinds of crops are consequently suffering considerably. Gardens, even of the youngest class, have a very old and withered appearance, and many of the usual delicacies of the season, of the vegetable kind, have come missing."

"*The weather, crops, &c.*—Never have we experienced such a continued spell of warm weather in Florida. For several weeks the atmosphere has been very oppressive. The thermometer ranged from 93° to 99°. No rain of any consequence has fallen in the mean time, and what little breeze we have had has been from off the land; hot and dry, like the Sirocco—withering all vegetation. Most of the crops in this vicinity, we fear, will fail. The fruit on the trees appears to be wilting, for the want of a few genial showers. But the city is, as usual, very healthy."—*St. Augustine, (Fa.,) June* 28.

According to the Jacksonville Statesman, the prospects of the planters in that portion of Florida are completely ruined. Every thing is perishing under the excessive heat and drought. The crops are withered to a crisp, the ponds and streams have dried up, and the cattle are dying for want of water.

Under date of July, we learn the following respecting the prospect in Louisiana:

"In Louisiana the drought is severe in some sections. The Baton Rouge Gazette says: 'The drought, for some time past, has dried up the corn and sugar cane. However, last week some parts of the parish were visited with showers highly beneficial to those in the favored range. On some plantations one half received repeated showers, while the other half is withering for want of the same benefit.'"

Nor was the drought confined to the Atlantic coast; it prevailed exten-

sively at the west; and even in August we meet with notices like the following:

The drought.—The Detroit Advertiser says: "This vicinity has, for some time, been suffering severely from the dry weather. The ground is perfectly parched. Grass and all growing crops are nearly dead from thirst. The prospect for fall feed and winter fodder is especially gloomy. The skies yesterday gave some promise of a shower, at least; but all signs fail in dry times. The weather is, also, oppressively hot; it has scarcely been more so during the summer."

Various statements are found in the public journals which show the extreme heat which prevailed, especially in the month of July, by which it appears that for days in succession the thermometer ranged from 87° up to 95°, and even 102° or 104°. The quantity of rain which fell, according to meteorological journals published, was unusually small.

We quote the following, as it presents a fair specimen of many other notices which might be given:

"The weather during the last week has been excessively hot and oppressive—beyond all former record—not only in this city, but also at different places from which we have heard. The range of the thermometer in the shade was, at Savannah, Georgia, from June 10th till the 24th, never below 90°. On the 23d and 24th it stood at 102°.

"In Charleston,	July 10,	94°
Boston,	12,	101
Rochester,	12,	97
New York,	12,	94
Philadelphia,	13,	101
New York,	13,	99
Albany,	13,	98
Brooklyn,	13,	95
Baltimore,	13,	95
Hartford,	13,	91
New York,	14,	98
Brooklyn,	14,	96."

From observation at Concord, New Hampshire, we learn, in the Farmers' Monthly Visitor of September 30th—

"From the 3d of July to 21st of August, there did not more than a quarter of an inch of rain, on what would moisten the ground about an inch deep, fall at any one time; the whole amount of rain between the two dates being less than one inch; the whole amount in July and August being about four inches, and three quarters of it fell the first three days of July, and the last week of August."

It is stated in the Genesee Farmer, published at Rochester, New York, that the "total amount of rain in June, July, and August, was 10 inches."

A journal kept at Athens, Georgia, and given in the Southern Cultivator, says: "The total amount of rain for March was 0.70; April, 0.12; May, 1.21; and June, 0.48 inch; for July, 3.60; August, 0.74; September, 0.58."

"In Chicago, from April 26 to May, 1.63; May 26 to June 27, 4.12; from July to August, 2.93; August to September, 1.53."

The quantity of rain noted at Louisville, Kentucky, in July, was 4.34 inches.

The ravages of insects do not seem to have been as great as in some former years; at least, the complaints of them in the public journals, and the notices of the crops furnished, are not so numerous. The army worm is mentioned as troublesome near Raleigh, North Carolina; in Michigan, Ionia county; also, in Wisconsin; and locusts in Missouri and Louisiana; the fly and weevil in some sections of the west, though not to the extent of former years. These will mostly be noticed in their proper place, under the respective crops thus suffering.

The damage by violent storms and tempests has also, it is believed, been less than usual, though occasional notices have met our eye of injury thus sustained.

On an inspection of the tabular estimate, it will be seen that wheat is raised in all the States except one—Louisiana. In the census statistics 69 bushels was put down to this State; but, as the amount was so trifling, it has not been deemed advisable to retain it. The amount raised in Rhode Island and Florida is also very small. Of barley it may be said, that though but a minor crop in most States, there are but two, Louisiana and Florida, where it is not numbered among the crops. Oats, Indian corn, potatoes, and hay, are more or less cultivated in every State of the Union; rye, to some extent, in all except in Florida; buckwheat, in twenty; hemp, in five; tobacco, in seventeen; rice, in eleven; silk, in greater or less degree, in nearly all; cotton, in fourteen States; and sugar, also, in almost every one.

In reviewing the crops we shall not adopt any uniform order of arrangement; though, in most cases, we shall be guided, in the form of procedure, by the rank the different States hold in relation to the product under notice, or geographical situation.

WHEAT.

The wheat crop of New York appears to have suffered but little from the extremes of the weather. On comparing the accounts at an early period of the growing season of the sections where the largest quantities are raised, we find them in general quite favorable. Thus as early as March, it is stated of the crop in Livingston county and vicinity, that the wheat looked "remarkably well." We meet with similar statements in April and May in respect to the western section of the State. As a specimen take the following:

"*Wheat* in this quarter is looking tolerably well; though the crop, generally speaking, is not as promising as that of last year."—*Canandaigua Rep.*

"*Wheat a coming.*—A friend showed us yesterday several perfectly formed heads of wheat of this season's growth, which, considering the generally low stage of the thermometer, may be considered a pretty fair development of the coming *wheat* crop."—*Rochester Adv.*

Again, early in June, the Genesee Democrat says that the crops in that vicinity looked "tolerably well." The Syracuse State Journal gives a similar testimony, as does likewise the Onondaga Standard; and the Ontario Repository mentions that the wheat crop was "improving;" and, "with an occasional exception, the fields give promise of a fair yield."

As the harvest advanced, we find under date of Syracuse, July 11—"The fields of wheat within sight are assuming a golden appearance, and in

the course of next week the reapers will commence gathering a most beautiful crop of a clear plump berry. Our opinion, formed by information from those who have abundant means of knowing, is, that the wheat crop of this State the present year will exceed that of last year at least one-quarter, if not one-third. The quantity will not only be larger, but the quality will exceed that of former years." The Newburgh Telegraph says: "Many fields have escaped the ravages of the *weevil*, a fly maggot, while a large number have been partially, and others wholly destroyed." "The wheat crop of Delaware county," it is stated in the Albany Argus, about the same time, "is represented as very fine." In the vicinity of New York it is also considered "very good." "The weather for securing it was for the most part uncommonly favorable."

In the month of August the accounts still continue to be for the most part favorable. Thus the Batavia Times says: "The wheat crop, which is of the most importance, is now secured in good order, and is in general very fair." And under date of Buffalo, August 1st, it is said:

"*Winter wheat.*—This crop has been all secured and in good order. The yield will be more than an average. But the total quantity raised will not be equal to the crop raised in 1839, which was *the crop.* Later, some suffered by the rust in some localities, but generally the crop is excellent. There was not as large a breadth laid down to wheat last fall as usual, and there will be still less this year. Two causes are operating: one, the price is too low; the other, many kinds of spring crops pay better, and that kind of tillage will not exhaust land so rapidly. Formerly it was the custom to sow wheat after wheat. It is now growing to be the custom to take a crop of wheat once in three or four years, stock down with clover, and alternate with pasture and spring grain. If followed for a few years, our wheat crop will excel anything that we have ever yet done in growing this grain. *Spring wheat* has suffered by reason of the drought, but will still yield a fair return." At a later date, August 11, we find similar statements: "The wheat crop, just harvested, as we have before had occasion to state, was one of unprecedented abundance."

The Danville Republican, speaking of the crop in the Genesee valley, says: "The crop is pronounced by all to be the best that ever grew in this valley."

The Plattsburgh Republican remarks, of the three northern counties, that the crop was very good. "Some of the finest fields of wheat" ever noticed in that part of the State, were observed in passing through Franklin and a part of Clinton county. In the interior of the State, and along the Mohawk in general, as well as south of these counties, the wheat crop was considered better than in the previous year. It is less necessary to pursue the detailed notices of the progress of the crop in this State, on account of being furnished with the statistics of the State census for 1844; and having thus a basis on which to learn, by comparison therewith, the probable increase or diminution. This has been done with considerable minuteness, and thus the conclusions drawn seem to deserve the character of more reliable estimates than for any previous year, except just after the census of 1840.

From information gathered since the harvest, it is believed that the gain on the crop of 1844, in the heavy wheat-growing counties of western New York, must have been from "20 to 25 per cent." In the southwestern section, bordering on Pennsylvania, the increase may not have been

quite so great; perhaps not more than 10 per cent. The season, however, was much more favorable—there was no rust. More towards the centre of the State, along Lake Ontario, and around the small interior lakes, as well still further south, and bordering on Pennsylvania, the report is not less favorable, and the gain is estimated at from 10 to 20 per cent.; and, in some cases, perhaps still higher. In the central eastern portion, along the Mohawk river, and extending south and north of this, the crop was much better than in the previous year, and the estimates, as variously given, are "15, 25, 33⅓, 50, and even 100 per cent." It may be recollected that great complaint has been made for several years past in some of the counties near the Mohawk river of the ravages of the weevil, which had nearly checked the cultivation of wheat there. The past year, however, this evil has been greatly lessened. Of Schoharie county, for example, it is said—"No injury from the weevil, which has heretofore destroyed the crop, and it is better in the ratio of a superior yield to an almost entire failure; the quantity of seed is larger than has been known in the best wheat-growing years." "The dry and warm season which brought the grain to maturity early, before the insect could prey upon it," is assigned as the probable cause. Of the crop in the adjoining county of Otsego, it is said that it was "nearly if not quite double the quantity of the crop of the year before. The weevil heretofore has prevented the sowing of wheat; but, as its ravages were less the previous summer, a greater quantity was sown and harvested last summer." There was likewise a "better preparation of the soil," and the quantity raised is "increased in proportion to the seed sown," and to the improved culture. In the northeastern section of the State, and bordering on Lake Champlain and the Hudson, the increase of the crop is estimated at "25 per cent." Lower down, however, in the vicinity of Rensselaer county, the drought operated unfavorably, and it is thought to have fallen off "10 per cent." The river counties have generally increased from 10 to 20 per cent., as they were not affected so much by the weevil and rust as in the previous year. In some cases there was less land tilled, but the quantity raised was greater, and the wheat was also of a better quality. Similar results are stated as to this crop on Long Island. Taking the whole State, therefore, we feel warranted in fixing the increase of the crop at a little above 20 per cent. more than that of the previous year. The census of 1844, which we have taken as the basis of our estimate, gave for that year 13,391,770 bushels, and the amount of acres thus cultivated 958,233 acres, which gives nearly an average of fourteen bushels per acre. We have compared the counties and notices respecting the growth of the crop and the harvest, as estimated by correspondents, with the census in detail, and thus feel more confidence in our estimate—meaning rather to fall short than to exceed the actual crop. There has been much more attention, on the whole, paid to the culture of this crop, and deep ploughing has in many cases been resorted to with the happiest effects.

Some interesting facts are mentioned in the Agricultural journals of large crops raised during the past year. Thus, to give a single specimen or two, the Genesee Farmer says: "The last harvest has turned out better than was expected at the time the grain was cut. We have seen a man who has spent most of his time for the last four weeks in threshing wheat with a machine, who says that nearly every farmer finds his yield

larger than he anticipated before it was measured. 'Mr. John Barber, of Farmington, took 1,500 bushels from 40 acres—an average of 37½ bushels. Thirty-three acres in Pittsford gave an average of 37 bushels. Sixteen acres in Brighton gave an average of 38 bushels per acre. Mr. Taft, of Greece, raised the past season thirty-six bushels of wheat on less than one-half acre of land. Seventy-two bushels per acre is a great crop.'"

This extraordinary growth is attributed to its having been manured with *horn shavings and scrapings*—Mr. Taft being a comb maker.

Some interesting remarks respecting the geological adaptation of the soil of portions of this State will be found in the appendix No. 2, among other papers relating to the culture of wheat hereafter mentioned. They are taken from an agricultural paper in this State.

Respecting the prospect for the coming year, we find the following observations in the correspondence of the Genesee Farmer:

"For one, I think the coming year will be a remarkable wheat season. My reasons are these: In the first place, the ground has been better prepared than I ever before knew it. Wherever I have been this fall, I have noticed a remarkable change in the preparing the ground for wheat, instead of the old method of getting it in, no matter in what condition. I have seen many who have adopted the proper mode of feeding the plant, with its natural ingredients, (such as lime, gypsum, ashes, charcoal, &c.,) and nearly all seem to think that wheat, in order to produce, should be so cultivated as to pay the cost of production, and that this cannot be done without preparing the ground in a proper manner. It has been one of the finest times for getting the seed into the ground, and having it germinate, that I ever knew; it seemed as if the rains came just often enough to start the seed, but not so much as to give it a sickly growth. I have noticed that, after a dry summer, we invariably have a good wheat season." The writer then recommends the employment of gypsum, as he supposes "the ammonia of the atmosphere, by collecting throughout the summer, and having but few chances to descend in showers, it comes at the proper time to benefit the young and growing crop;" and hence it is desirable to absorb it and hold it for the use of the crop. The editor of the Farmer, in some remarks, also approves the suggestions, and recommends, with such view, the use of plaster, ashes, and charcoal, as a top dressing in the fall or the winter, and says that "in travelling through many counties in the State, he never saw the wheat crop look better."

The wheat crop of Ohio, according to the notices we have gathered, was subjected to considerable vicissitudes in the early periods of the season. The following are some of the statements:

The Ohio Statesman of the 7th April, speaking of the cold weather, says: "The cold dry weather is favorable to the wheat crop, which looks very fine generally." The State Journal, published at Columbus, under date of 23d April, speaks of the "wheat fields as suffering severely from the protracted drought." "Several fields of wheat in the neighborhood of that city (it states) have been abandoned as worthless; and in most of the fields it has a sickly yellow appearance."

The Cleveland Plaindealer, of 1st May, remarks: "We have conversed with farmers from distant points along the lake shores, who tell us that the late rains have so improved the appearance of the crops, that they expect an average of wheat." In the Ohio Cultivator of the same date, after mentioning the severe drought, and a partial relief from a slight fall

of rain, it is stated: "The wheat crop, however, is not as generally injured as was at one time anticipated. We know of some fields that are quite destroyed by the conjoined effects of frost and drought; but such cases are not numerous. Most of the fields in this region are more or less thinned and killed in spots; though the plenteous rains of the past few days are giving them good color, and they look finely to the passers by. If the season proves favorable, the wheat crop of the State may yet be a good one."

The Ravenna Star also mentions the frosts and drought, and says: "Wheat and spring wheat seem likely to prove very light unless the continued unfavorable weather should render them a total failure."

A correspondent of a public journal from Newark, Licking county, writes, under date of 27th May: "Wheat, much of it, is suffering for rain, and in low places is injured by frosts." The Dayton Journal says, however, that "there is reason to hope the crop will be abundant in that section."

"It looks well about here," says the Toledo Blade. The Clinton Republican estimates, during the same month, that "there will not be more than half a crop of wheat." The Columbus State Journal, of the 29th and 31st of May, declares: "It is now almost certain that the wheat crop in that section of the State, and north to the lakes, is injured beyond recovery by the frost and drought. The crop, under any circumstances, will not be more than an average one." The wheat fields, with here and there an exception, look bad. With a majority of our farmers, the prospect of the wheat crop is hopeless. The frost of the 29th is mentioned as "one of the severest spring frosts ever known, cutting everything within its reach to the ground." The Findlay Farmer, of 27th May, says: "The severe drought is doing much injury to the wheat crop. Wheat is beginning to head, and some of it is not over a foot in height." Similar is the report given about that time by the Mansfield Shield and Banner, and by the Trumbull Democrat, in which apprehensions are expressed that there will not be more than half a crop. The Cincinnati Gazette, however, speaks more encouragingly about the same time: "We hear of some complaints in Ohio; but we think, from all we can gather, that we shall have an average wheat crop. Such is the promise now; and that promise is increased by the present weather. Rain is falling fast; and the dry earth is drinking it up as if athirst. Some sections have suffered severely from the drought; for instance, around Columbus and Mount Pleasant, in this county. In the latter they have had, until within the last two days, only three dashes of rain since February." With allowance, however, for diversity of opinion, there can be but little doubt that the wheat crop appeared most unpromising through the month of May. In the Ohio Statesman we find the following account respecting the wheat in their respective counties in this State, as furnished by the members of the grand jury during their attendance on the United States court, viz:

Lorain county—"about one-fourth of a crop."

Clermont—"the best for ten years."

Lake—"about the same as last year; not so much straw, but better filled, and the wheat much heavier."

Starke county—"will yield little more than half a crop; suffered greatly by the late frosts and dry weather. The grain, however, will be vastly better than last year, being full and plump."

Higland county—" a better crop than since 1839; not so much straw as usual, but well filled and heavy."

Tuscarawas county—" in the plains and river bottoms not half a crop of wheat; on the ridges more than half a crop; but not an average crop on the whole."

Richland county—" somewhat injured by frost and drought. Farmers think there will be as much wheat cut as last year, although more was sown."

Meigs county—" unusually good; this year better than I have known it for the last twenty years. Some fields in the northwestern part of the county, where the soil is of a cold clayey nature, were injured some by the late frosts."

Fairfield county—" crop about on an average; grain plump and full."

Guernsey county—" considerably injured by frost, although a full average crop, and the grain unusually full and plump."

Hamilton county—" crop in this county is larger than an average; the berry large and sound, and universally heavy, calculated to make flour of the best quality." Warren, Butler, and Preble, reported to be similar to Hamilton.

Greene county—" the greatest abundance of *wheat* ever known before, and of the best quality."

From the above it would appear that in the southwestern and southern central section the crop was very good, while in the northern central and northeast, towards the lake, it was not so good.

The month of June dispelled much of the apprehension which had existed respecting the wheat crop of Ohio; as the harvest came on, the accounts from all sections brightened. Thus we find such notices as the following:

" The crop is greatly injured, and field after field mostly ruined; yet there may be more wheat than the most sanguine have hoped for."—*Ohio Statesman, June* 2.

Again: " As for wheat, there is a much better prospect than a week or ten days ago. Though the crop will be short in Ohio, there is no danger of a famine. From many parts of the country the papers speak of fair wheat crops." " The wheat and grass crops were so far advanced that they must be quite light in most parts of the State, although the rains will greatly benefit them, and the yield will be better generally than was anticipated. Being light in straw, wheat will be less liable to suffer from rust than is usual; so that the yield may be as great, if not greater, than for several years past, especially in the central and southern parts of the State."

[From the Cincinnati Gazette.

Crops in the Scioto valley, Ohio.—A good judge, lately visiting this valley, writes us as follows:

" In going from Columbus to Portsmouth, I was much pleased to find that all portions of our fine valley have not suffered as much from the effects of cold and drought as the region about Columbus. From Circleville, south, the wheat along the valley promises fair; it is light in straw, but will be less likely to suffer from rust than if of strong growth, as last year."

"The wheat crop is much changed for the better; so that the panic created by the extreme drought is now at an end. The wheat, however, in this region, must be far below an average crop."—*Mount Vernon (Ohio) Times, 20th June.*

The Dayton Journal says: "Within the last two weeks, a most favorable change has taken place in the prospects of the farmer. The wheat has improved wonderfully, and there is no doubt but that the crop in this county will be greater than an average one. We have conversed with a number of farmers within a few days past, and all agree in the fact stated. The wheat has headed finely, and the berry is remarkably plump and heavy; so that the yield will not only be more abundant than usual, but the grain will be of a superior quality. If the farmer should have favorable weather for securing his crop, he will be amply repaid for his toil."

In relation to Allen county, the Lima Reporter says: "During the past ten days the weather has been as seasonable, and vegetation has grown as fine, as heart could wish. We have lately had copious and refreshing showers; and, instead of a famine, as some unnecessarily feared, we have now the fair prospect of a fine harvest. It is the general opinion of the people now, that there will be more wheat raised in the county this year than last." A correspondent from Champaign county, of June 28, thus writes to a friend in this city: "The wheat crop has come out beyond all our expectations; it is filled very plump."—*Cleveland Herald.*

Again: The Circleville (Ohio) Herald, of the 6th of June, gives a more favorable account of the crops in that section of Ohio. It says: "The injury is not so general as we had feared. We are informed that in some portions of the country the wheat crop will be an average one, and in others from one-half to two-thirds will be realized. The near approach of the harvest renders any attempt now to misrepresent the state of the crops useless." The Columbus Journal speaks of the wheat crop in that section as "heading well, and the grain better than it has been for many years. Occasionally a field may be seen in which the grain is worthless. In Muskingum and Licking, the wheat crop will be better than was expected. In Morgan better than it was last year." A gentleman from Washington county, Ohio, informs the Columbus Journal, that "the wheat crop in the Muskingum valley will double that of last year. In his own county, the farmers had nearly finished harvesting when he left, and they were able to speak with certainty as to the character of the crop."

"The wheat harvest has commenced earlier, we believe, than was ever before known in this country. We understand they were harvesting wheat in Groton a week ago. The crop is heavier than was expected a few weeks ago, and the grain is good. Late rains give us a prospect of other crops."—*Sandusky (O.) Clarion, June.*

"We have had a favorable change in the weather within the last two weeks past, which has wonderfully improved the appearance of the wheat crop. In some of the townships we heard it stated that the crop will be an average with the last two years as to quantity, while the quality will be quite superior. If the farmer shall have favorable weather for securing his crops, the yield will be abundant."—*Painesville Telegraph, June 25.*

"The abundant rains with which the country has been blessed during the last ten or twelve days have very much improved the crops in this section, and indeed throughout the State. From what we are able to gather from our exchanges, we think there will be full two-thirds of an average yield of wheat in the State. In Erie county we have heard that

the wheat crop will be nearly if not quite as large as last year. The quantity in this county will be much larger than any one anticipated two weeks ago—more, probably, than will be needed for home consumption."—*Huron Reflector*, *June* 25.

The accounts in July are generally more flattering, as the weather was more favorable for the harvest. Still some of the sections suffered from the previous drought and cold. We throw together a number of notices with reference to various parts of the State, as given in some of the public journals during the month of July:

"Within the last two weeks a most favorable change has taken place in the prospects of the farmer. The wheat has improved wonderfully, and there is no doubt but that the crop in this (Montgomery) county will be greater than an average one."—*Dayton Journal.*

"We are told by many of the farmers that the yield of wheat will be twice as great this year as last."—*Xenia Torchlight.*

"The farmers are now very busy with their wheat. The crop to be secured is better than any which has been raised for the last ten years."—*Dayton Journal.*

"The wheat, we are told, is generally very well filled; but that cut before the rain has in many instances grown."—*Butler County Journal.*

"From what we can learn, the crop in old Muskingum county, this season, will no doubt exceed that of the last, which was little over half a crop, and the quality is far superior. Indeed, it is said that the grain cannot be surpassed for size and plumpness."—*Zanesville Republican.*

"Our wheat crop will be probably better than it has been for the last four years."—*Highland Co. Gazette.*

"A person from Williams county, Ohio, informs us that the crops there look fine. Wheat is better than it has been for many years.

"With occasional fine showers, we have had sufficient dry weather to enable farmers to harvest their wheat in good order. South of this it is nearly all secured. In this region it is nearly all cut, excepting where fields were injured by frost, and a second growth of heads put forth; patches of this kind are in some cases struck with rust, but as a whole the quality of the crop is remarkably fine. The quantity is not large, though as great, we believe, as the average for several years past. The same, we learn, is the case in most of the eastern counties along the Ohio river; also in the western portion of the State; but in the central northern counties, including most of the best wheat region, the crop is said to be very deficient. The Cleveland papers complain of severe drought in that region at the present time."—*Ohio Cultivator*, *July* 15.

Again, in the same paper of another date: "The wheat, too, that was not killed by frost, has filled out more plump and heavy than has been known for many years in these parts, and the yield, though very light in straw, will, it is judged, be greater than for two or three years past; though this is not the case in many of the more northern counties, where the most wheat is commonly produced."

"The panic created among the farmers of this vicinity, and among others, has to a great extent ceased; at least so far as Pickaway county is concerned. From present appearances, we assert that the yield of wheat in this county will be larger, and the grain better than the crop has been for the last four years."—*Guard and Pilot.*

"The journals of last week, in Jefferson, Ross, Muskingum, Licking,

Fairfield, Franklin, Clark, Greene, Montgomery, Warren, and Hamilton counties, all speak of the harvest having been partly secured, and pronounce the wheat crop as good or better than for some years past. The quality of the grain very superior.

"We are glad to hear, by our country exchanges, that the wheat crop has most agreeably disappointed the farmers. The smallness of the stock has been made up by the plumpness and fullness of the grain. Even in Starke county, and others in the neighborhood, where the crop was supposed to be badly destroyed, it turned out to be very good. In the Miami country it never was better."—*Cincinnati Chronicle*, 11*th inst.*

The St. Clairsville Gazette (Belmont county) says: "The yield is not large in this county, but what we have is excellent; we have seen samples that weighed 68 and 70 pounds to the bushel."

The Milan Tribune says: "The wheat harvest is about over, and a fine time the farmers have had."

The accounts received at a still later date, and since the harvest has been fully gathered, exhibit much diversity, and in some instances appear to be at variance with the foregoing.

From the counties lying north of the centre and along Lake Erie, we learn that the drought so much affected the crop as to lessen it at least "33 per cent." The crop also in the counties northeast of the central, comprising Wayne, Starke, &c., are said likewise to have suffered severely, and the crop is considered to have been "30 per cent. less." The counties adjoining these, bordering on Pennsylvania and the Ohio river, are likewise estimated to have suffered at least "30 per cent." Of the north central counties, comprising Delaware, Marion, and Richland, it is said that "wheat was a poor crop in 1844, and much worse in 1845. In many townships the yield did not return the seed. The Hessian fly did not much injure the crop of 1845, but the warm and pleasant fall which we have just passed has favored and extended the ravages of this insect upon the growing crop." The loss is estimated at "50 per cent.," and by one correspondent the damage has been put as high as "70 per cent." In the southeastern section, from the centre of the State, the crop is thought to have been "better by ten per cent." Further to the north it is said to be one-third less. In the upper part of the Scioto valley, just south of the central counties, the crop is considered as fully equal to that of the previous year. In the Miami valley and the southwestern counties of the State, bordering on Indiana, it is estimated to have been from 25 to 30 per cent. better than in 1844. A good judge, speaking of the centre of the Miami valley, says: "Much apprehension was felt during the early part of the season, on account of late frosts and protracted drought, that the crop would prove a failure, but the grain filled out well, and was almost entirely free from smut and rust." He thinks it to have been "30 per cent. better" than in the previous year. In the northwestern counties bordering on Indiana, Michigan, and along the Miami river, the crop was much better; and it is estimated even as high as "50 per cent. more." In the section along Lake Erie, east of these last counties, also, the decrease is thought to have been "25 per cent."

In the Albany Cultivator of January, 1846, a correspondent from Zanesville writes thus, respecting the crop in some of the counties heretofore named, which gives a somewhat different view from that which is mentioned above. He says:

8

"On all flat lands in the northern part of Licking, parts of Delaware and Franklin, and considerable portions of the adjoining counties north, the wheat crop of last season was almost a total failure, in consequence of a frost the 29th of May. I am told that the farmers now have to buy their wheat for family use; and many, who early in the spring thought their prospects good for a crop of 400 to 600 bushels, did not get even so much as their seed."

In Muskingum county they think they have little more than half of an average crop of wheat; but what there is, is of a superior quality."

A good judge writes respecting Muskingum county and its vicinity:

"At your request, I give you my views of the general character of the wheat crops of 1844 and 1845 in this vicinity; and by 'this vicinity,' I mean the region of country supplying the mills here with wheat.

"The breadth of wheat sown in the fall of 1843 was very large, and the prospect for a good crop unusually propitious until the time of the wheat blooming.

"Just at this most critical juncture, we had a succession of wet, stormy weather, for two or three weeks; so much so as to damage the crop in quantity to the extent of *one-half;* and the quality, also, was *very much* deteriorated, the average weight not exceeding 53 lbs. per bushel. On the whole, I consider the wheat crop of 1844 in this vicinity less than *one-half* of an average.

"In the fall of 1844 the breadth of wheat sown was somewhat less than in the previous year. The appearance of the wheat on the ground in the early spring was also less propitious; still the prospect was tolerably good, and the crop would probably have been an average one, but for two or three very severe frosts which occurred in the month of May—the first about the middle of the month, and the last towards the close.

"The effects of these frosts were immediately visible, and great fear was entertained that this vicinity (and, indeed, the whole of Ohio) would not yield sufficient for consumption and seed. Thousands of acres were not worth cutting at the time of harvest, and thousands more hardly repaid the labor of saving and threshing.

"So far as I can at present judge, the crop in this vicinity will not be over *one-third* of an average, and certainly not one-half. The quality is fair, weighing generally from 58 to 60 lbs. per bushel; some of the wheat partially injured by the frosts weighs very light—say 52 to 54 lbs. per bushel.

"The prospect for the coming harvest (1846) is at present very encouraging; the quantity sown last fall was unusually large; and farmers, having been disappointed in their hopes for three successive years, took more pains in seeding than perhaps ever before in this vicinity. The season, also, was unusually propitious during the time of seeding, and has continued so up to the present moment.

"The foregoing are my views in regard to the two wheat crops of 1844 and 1845; and, during the whole of my experience, I never witnessed any thing to be compared with them. In 1844 the quality (in addition to a deficiency of nearly one-half) was such as to render it impossible to make a good quality of flour; and in 1845, although the quality is fair, the quantity is probably not more than *one-third* of an average."

It will be seen, therefore, that the drought affected some sections of the State far more than others. A comparison has been made anew with the

census of 1840, to ascertain as carefully as possible what sections have yielded the greatest amount of wheat, as also the population; and, after the best investigation of the causes operating on the crop of 1845, it is believed that it must be fixed at about 15 per cent. decrease from the previous year. This conclusion may not correspond with that of some; but it is hoped that those who are disposed to decry it will at least do us the justice to go through, in detail, as full a collection of notes and as extended a comparison as we have done. It will be seen, by a reference to the report for that year, that the crop of 1842 was a very large one, and that there has been a falling off from that year on account of the rust, &c.; yet it is believed there has likewise been a gradual increase of the quantity of land sown with wheat, and the modifying influence of this element must be allowed to balance, so far as proper, the decrease. It is not improbable that the deficiency of last year, (1844,) compared with the crop of 1842, may have been somewhat too large, and regard has been had to this consideration in fixing upon the estimate in the table; and thus the proportion which the present one bears to that of 1844 is different from what it might otherwise have been.

The early notices respecting the wheat crop in the great State of Pennsylvania, which stands among the first in the culture of this grain, were, on the whole, favorable. In April, the Germantown Telegraph says:

"The grain looks well in all directions; and, should ordinary favorable weather continue for the ensuing month or six weeks, a heavy crop of wheat may be anticipated."

Early in May, also, we observe the following notices:

"The appearance of the *grain* now indicates an abundant and plentiful reward for the husbandman's toil."—*Lewistown (Pa.) Democrat.*

The editor of the Newtown Journal, who has been taking a tour through part of Bucks, Montgomery, Philadelphia, and Delaware counties, Pennsylvania, notices the fine appearance of all kinds of vegetation: "The *wheat* crop, especially, looks unusually fine. Several old farmers in the vicinity of the Brandywine say they never saw a finer prospect of winter grain."

"*Lock Haven, (Pa.,) May* 10.—In our own immediate vicinity the *grain* fields look exceedingly promising."

Lancaster, Pa.—The Intelligencer says: "Never within recollection has this great agricultural county given promise of more abundant crops than in the present season. The late rains came most opportunely, and there is little doubt now of the utmost abundance in all the products of the soil."

Somewhat later, there is complaint made, in some sections, of drought, and a frost in the last week of May, by which the wheat crop was considerably injured. Thus the Western Star, of Beaver county, (Pa.,) of June 6th, says: "We are sorry to say that the reports of our farmers now in attendance on court from different parts of the county, respecting the damage done to the wheat and rye crops by the late frosts, are of the most discouraging nature. A few days more will disclose the extent of the mischief. Owing to the long-continued drought, the crops would have been light without frosts; but if the grain be killed, as is stated, it will prove a serious calamity. The farmers must endeavor to provide for the deficiency by sowing and planting buckwheat and potatoes."

"*The damage from frost.*—We have before us a letter from a corres-

pondent at Lancaster, in this State, by which we learn that the frost of Thursday and Friday nights of last week was even more disastrous to the *wheat* crop of that county and of Chester county than it was in the immediate vicinity of this city. Many fields have been damaged, and some entirely destroyed. The effects of the frost were more fatal in consequence of the enfeebled state of vegetation from long drought."—*Philadelphia Ledger.*

In a communication to the Farmers' Cabinet, from Chester county, it is stated that the damage was mostly to the Mediterranean variety, that being earlier than some others. A portion of this statement is subjoined, as it contains some interesting facts. The thermometer is thought to have been as low as 30°.

"The most severe loss falls on our wheat fields. The wheat mostly grown about here is the Mediterranean, which is a very early variety. The crops were quite promising, and our farmers calculated confidently on more than an average yield; but those hopes were unexpectedly cut off. Most of our wheat was in blossom. I had walked through a fine field within a day or two of the frost, in company with one of our farmers, and we were admiring the regularity of the blossoms on the plants. The morning after the frost, he observed to me that it was his opinion such a night would kill the wheat. Within forty-eight hours the evident tinge of brown, which showed deeply in the hollows and faded away up the hill sides, proved that his fears were well founded. The idea of a frost, so late in the season, injuring so hardy a plant as wheat, was new to most of us, but we had to admit the fact since it was so plainly before us. It is evident that the action of the frost was entirely on the *blossom;* the plant itself is yet as healthy looking as ever, but no grain has formed. Such an occurrence is so unusual as to be almost unknown to farmers; and, indeed, most with whom I have conversed on the subject were inclined to doubt its having ever occurred, though a few think it did happen slightly two years ago, in their neighborhood. The effect of trees in protecting grain is not a little remarkable. Woodland, on the north, served to keep off the frost some distance beyond where the shade of the trees would be cast in the day; and, in one instance, a small grove of chestnuts in the bottom of a hollow, where the frost was the heaviest, completely protected the wheat for many yards beyond the shadow of the trees. A small patch of potatoes, which ran up into some woodland, forcibly illustrated this, also; under the trees the tops of the plants were untouched—further from them they were just tipped; while, further, portions of them were cut to the ground.

"On the higher hills many escaped untouched, and those which were injured suffered but slightly. The Mediterranean wheat was almost the only kind injured, though in some places some other varieties did not escape; the later kinds around us promise a very fine yield, having escaped by not being in blossom at the time. Some of our farmers cut down their wheat, so fully were they convinced of the destruction of their crops. This was the case in Doe Run and East Marlborough townships, and probably in other places."

The editor of the Cabinet adds in a note—"We have understood from different neighborhoods that the wheat affected by this frost was generally, though perhaps not quite exclusively, the Mediterranean. This is an early ripener; and it is possible that this circumstance, subject as we are

occasionally to pretty hard frosts late in the season, may prove a serious objection to it."

As the harvest came, the accounts continued more favorable. The Adams Sentinel, published at Gettysburg, says: "Our farmers are in the midst of a plentiful harvest. We learn that the crop of wheat in this county is much better than it has been for many years."

The Germantown Telegraph of July 2 has the following statement: "The Westchester Register of July 1 states, 'that many of the fields of wheat in the vicinity appear ready for the sickle. If the weather is fair there will be much grain cut and housed the present week. The grain harvesting has commenced in earnest, and about a week in advance of the usual period. The crop of wheat is estimated to be a full average yield.'"

Again: "A gentleman from Washington county informs the Pittsburg Gazette that a good deal of the wheat, particularly the Mediterranean, has been cut in that county. This species of wheat has turned out exceedingly well—given large and fine crops. Its appearance is somewhat remarkable beside our common wheat, and the heads are very well filled." —*July*.

Similar to the above are the notices found in the papers respecting the crop in general of this State. "The wheat harvest in Pennsylvania is the best we have had in many years. The crops are heavier, cleaner, and freer from rust than they usually are. The crops in Pennsylvania are, it seems, above the average." The Harrisburgh Union says: "Almost every paper we open from the interior of the State speaks favorably of the late crops. We learn that the harvest is now over, and the *wheat* crop is said to be one of the heaviest and most abundant that has been gathered for many years. The quality of the grain is decidedly superior."

The information derived from others also corresponds with the foregoing. Of the crop in the well known agricultural county of Lancaster, it is said: "The mild weather in the month of March and the beginning of April was so favorable to vegetation, that it was apprehended the growth of wheat in our productive and highly cultivated lands would be so luxuriant as to cause it to fall before the grain was matured, and thus occasion a deficiency in quality and quantity; but a continued spell of dry weather during the months of April and May retarded the growth of the plants, and prevented the exuberance that had been anticipated. On the 29th of May the prospect of an abundant crop was as flattering as the heart of man could desire, but on that night a severe frost occurred which blighted the prospects of many of our industrious and thrifty farmers. Hundreds of acres were so completely destroyed that they would not compensate the laborer for cutting it. That which grew on low level lands sustained the greatest injury, particularly where situated contiguous to streams of water. That species or variety of wheat called the 'Mediterranean,' which was introduced into our country a few years ago, being an early wheat, capable of withstanding the attacks of the Hessian fly, and less subject to injury from mildew and rust than others, suffered most from the effects of the frost, from the circumstance of its being further advanced, and in the condition where the tender blossom of the berry was exposed, or in consequence of its being more tender and less able to endure the intensity of the cold. I am inclined to attribute it to the former cause, as that wheat principally was all out in heads, and fairly

exposed, whilst a large part of the other was still enclosed in the folds of the blade leaf of the stalk, and in some degree protected from the violence of the weather. From that time until harvest, the weather proved favorable to the maturing of the crop; the heads were well filled, and the berries plump and fair, so that it remained uninjured by the frost; the yield was abundant, and the quality superior. And it is believed that the aggregate of the wheat crop throughout the county will fully equal that of 1844."

The account communicated to us from Chester county fixes the increase of the crop over that of 1844 at "25 per cent." The following are some of the remarks made in the letter: "The wheat crop of the present year is a good average. Some fields in low situations were injured by frost about the first of June, when in blossom, but the large amount sown, and the good yield, fully supplied the loss. Much of the wheat yields a bushel to a dozen sheaves of ordinary size, and weighs sixty-five pounds to the bushel. The Mediterranean is more extensively cultivated than any other, chiefly because of its exemption from the depredations of the Hessian fly. It is very much improved in quality since its introduction here, and is now esteemed as highly as any other red wheat. It has in some instances been injured by the fly, and it is not probable that it will much longer resist their attacks, unless fresh seed be brought from abroad. The Hershe, and some other varieties of white and red wheat, are also cultivated to some extent." In other parts of the southeastern section of the State it is said: "The quantity is about the same, but the quality is equivalent to an increase of 10 per cent." In the eastern counties bordering on the Delaware river, and towards the centre of the State, including Bucks and Lehigh, the increase is estimated at about "10 per cent." The injury by the frost is complained of, especially in Lehigh county; but it is added, that "there was no blight, and what escaped the frost yielded well." In the south central section, bordering on the Susquehannah river and the Maryland line, the crop is considered to have been "50 per cent. better." There was "a favorable winter, and a dry March and April, with a favorable time for the filling season. No mildew or rust, and great freedom from the fly." In the central counties, lying on the Susquehannah and its branches, the crop is stated to have probably exceeded that of 1844 by "one-third." Northeast of these the gain does not seem to have been so great, and it is estimated at from 5 to 10 per cent., and the grain is described as being "very good, plump, and heavy." In the northwestern part of the State there was an advance of "about 10 per cent., but the crop of neither year could be considered a full crop." Our information respecting the crop in the southwestern, the northern and southern central sections, is not as good; but so far as we have been able to ascertain, there has been an increase in almost all parts of the State. It is believed that the advance of 20 per cent. on the crop of the preceding year, which was one attended with considerable blight and rust, will not be too great, if it is indeed large enough.

Virginia is also among the largest wheat-growing States. The early appearance of the crop in this State did not promise much, but the fears of the agriculturist were happily not realized.

In the months of March and April, mention is made of the drought and frost in many parts of the State. In Rockingham, however, the public journals speak of refreshing rain, the influence of which was felt on the vege-

tation generally, and "the crops of small grain, especially," were "greatly benefited." So that there seemed to be "the most promising assurance of a bountiful harvest."

The Richmond Whig, under date of April 20, says: "We regret to learn that the destruction of wheat by the late frosts was much greater than we supposed." And, in May, again: "Much of the May wheat was irreparably injured, but the late wheat bids fair to give an average yield."

The Petersburg Intelligencer, likewise, during the same month, states: "The wheat crops in the James river country, above tide water, have been damaged seriously by the frost and dry weather."

Again: The last Rockingham Register, speaking of the late severe frost, says: "We learn that in some parts of this county, the wheat crop, which a few weeks ago presented such a cheering prospect of harvest, has been almost totally destroyed. The damage done to the wheat by the frost in Augusta, we understand, is much more extensive than was at first supposed, particularly along the water-courses."

The Richmond (Va.) Times says: "We are glad to learn from the wheat-growing sections of the State that the wheat crop is far better than, a few weeks since, it was supposed it could possibly be. Even the early May wheat, which was thought to have been ruined by the frosts of the 9th April, and the cold dry weather thereabouts, has started forth under the invigorating influence of the genial weather for some time past, and now promises a yield fully equal to half a crop.

"The *wheat* crop of the lower James river region suffers more than in other parts of the State. There, a large proportion of the early wheat is cultivated, and there the crop of all kinds of wheat is earlier than in the middle and valley districts; therefore it was most injured by the frosts of April.

"Our accounts from the valley represent the *wheat* crop to be unusually fine and promising."

"All the May wheat—and the culture of that species has become quite general—has been frosted so as to destroy full half of that portion of the crop. Some fields I have seen look yellow, as though harvest was as hand."—*Richmond Whig.*

"The weather continues dry, with no appearance of rain. It also continues cold, especially at night. We learn that there is danger of the *wheat* crop, especially on the hills. The Richmond Enquirer says, that all the fruits of that region have been touched by the late frost, and that the wheat has not escaped."

Toward the close of May, and in the season of harvest in June, however, as well as subsequent, the accounts are more favorable.

"The prospect for a fine crop of wheat in this vicinity, at present, is excellent. The grain looks well, and the opinion is generally entertained that if no untoward circumstances occur, the yield will be unusually heavy."—*Harrisonburg (Va.) Republican, May* 17.

The Richmond Compiler says: "Some few farmers in this neighborhood have cut their May wheat, and represent the quality as very superior, and the yield about an average one—greatly better than was expected. The late wheat promises even better, and, should it receive no injury in the brief space before harvest, will be a very fine crop. The harvest for the late wheat will begin about the 10th or 12th instant. No contracts

for wheat have been made, and we believe this year none will be entered into. We have not had rain for some time, and vegetation begins to suffer in this vicinity."

Again: "We have had several very refreshing rains in the last week or two—enough, as we have been informed by several of our farmers, to make the wheat."—*Martinsburgh Gazette.*

"Harvesting has commenced in this section, and generally we believe the wheat crop will turn out well, notwithstanding the inauspicious promise of the early spring."—*Lynchburg Virginian.*

"Our farmers have commenced securing the early wheat, the quality of which is generally very good—indeed, from present appearances, the crop will generally be of good quality. At this season of the year there is a good deal said about the quantity. We think from what we can learn, and our information can be relied upon, that there will be an average crop, and perhaps more than for several years past."—*Virginia paper.*

"Several of our farmers are already cutting their Mediterranean wheat; and, from present appearances, we are inclined to think the general harvest will be earlier than usual. The prospect is tolerably fair."—*Ib.*

"The Richmond Compiler says that the growing grain in the southern section of Virginia has nearly recovered from the effects of the drought; and that the May *wheat*, though much injured by the frosts, will yield very well."—*Winchester Republican.*

The Southern Planter says: "As far as our observation has extended, the cold and unfavorable season has affected the growing crops most seriously. The wheat, which was cut down by the frost, has measurably recovered; and, as it was a novel case, it would, perhaps, be as well for our correspondents to record their experience upon the subject. For ourselves, we believe, if it had not been for the drought which followed the frost, the young shoots would have put forth with sufficient vigor to have fully supplied the place of those that were killed. As it was, the crop of early wheat will be more than half a one, and the late crop is very promising."

In other public journals we find similar notices, sometimes without reference to the particular sections.

"The wheat crop this season, in Frederick county, Virginia, is said to be the heaviest that has been harvested for many seasons."

"*Wheat* harvesting has commenced in this State, and the crops, with the exception of the May wheat, are said to be very good." The Richmond (Virginia) Times says: "The wheat crop will be fully an average one; the frost has not injured the wheat." "The *wheat* crop has been all gathered in excellent condition, and is more than the usual average." So far as we have been able to ascertain from other sources, the result of the harvest corresponded with the foregoing statements. We have not as full information as could be desired, owing to the failure of answers to our circular, in season for the present estimate. In the section east of the Blue Ridge, lying in the central part of the State, from Bedford through to Orange counties, and which appears, from the census of 1840, to comprise some counties where large quantities of wheat are grown, it is said: "The crop is exceedingly fine in quality, and fully an average in quantity. It was somewhat injured by the late frost last spring; but except as to the very early May wheat, the damage was slight." As the crop in

this section fell off so largely in 1842, and but just recovered its amount, as exhibited by the estimate of 1844, we believe that an average crop will exhibit some advance for the past year. In the counties east of the last mentioned section, it is said: "Wheat in quantity was about the same as in 1844, but in quality it was 10 per cent. superior." The southern central counties, from Halifax and Franklin, along the line of North Carolina, are thought to have exhibited an increase of "25 per cent." The northwestern section of the State also appears to have harvested a good crop, as it is thought there to have been "25 per cent. better." In the western section, lying on the Kanawha river and its branches, and south of the last mentioned, the increase is likewise estimated at "25 per cent." above that of 1844. Taking into view the early condition of this crop, it is believed that we are justified in fixing the increase of the crop at 10 per cent. above that of the previous year. The editor of the American Farmer, speaking of the Virginia wheat crop, says: "Though disasters have occurred to blight the prospects of particular regions, we entertain the belief that the wheat crop, on the whole, will prove more than a fair average one." A correspondent of the large wheat-growing region in the valley country says, likewise: "The wheat crop is a good one—the first good one we have had since 1839." Another public journal, alluding to the general crop in Virginia, says: "The crop is decidedly above an average one."

Respecting the Maryland wheat crop, we have gathered the following information. The appearance during the month of March was considered most flattering. As a specimen of the statements contained in the public journals, we give the subjoined:

"The accounts from all round the country represent the wheat crops to be in a most thriving condition. The fields are as green as is usual on the first of May. It is too early to make any certain calculation of the next harvest; but the indications have never been more favorable at any season than they are now."—*Baltimore Patriot.*

"The appearance at present presented by the growing crops of wheat could not possibly be more promising. They possess all the cheerful verdure and vigor which is usually distinguished at the close of the present month, and, unless retarded in growth, we may calculate upon one of the finest crops we have ever had."—*Hagerstown (Md.) Torchlight.*

Again: In April, the Easton (Talbot county) Gazette says, that the *wheat* crop presents a very promising appearance. The Williamsport Banner says: "The *grain* crops of Washington county have never, within our recollection, presented as beautiful and flourishing an appearance as at this time. They bid fair to yield the farmer a plentiful harvest." Somewhat later, however, the Williamsport Banner says: "In consequence of the continued drought the wheat crop does not present as flourishing an appearance as it did last week." The view of the wheat crop in May is, on the whole, most favorable, though some diversity exists in particular sections.

"We learn that the *wheat* looks well in Talbot county, being from fifteen to twenty inches high on a level, a few days since. Some wheat there is stated to have reached the height of four feet, and all headed out. The Weekly Sentinel, published at Centreville, Queen Anne county, says: 'For several days past we have had most delightful weather for the growing *wheat*. The prospect for a good crop could not be more favorable.'"—*Baltimore Sun.*

A letter from Talbot county (Md.) says: " *Wheat* looks well here, and there is a prospect of fine crops, it being from fifteen to twenty inches high on a level. I have heard of some wheat in this neighborhood four feet high, all headed out."

The Port Tobacco (Charles county, Md.) Times says: "The *wheat* crop looks well; and, unless attacked by rust, fly, or some of the many ills that sometimes carry it off, bids fair to produce a good yield."

Again: "We learn from friend John Poland, of the Westernport district, that the crops, and vegetation generally, present quite a different aspect in that region since the refreshing rains some days since. The prospect of a good crop is very flattering. Indications from other parts of the country are equally so.

"Accounts from various sections of the country indicate a like glowing prospect. The editor of the 'Catoctin Whig,' of Middletown, in this State, says he has conversed with many of the farmers of old Middletown valley, one of the best grain-growing regions in the country, who entertain the highest hopes of an abundant yield of every kind of grain."—*Cumberland (Md.) Civilian, May* 1.

The Westminster (Md.) Carrolltonian says: "The whole crop in this county generally presents a remarkably fine appearance; and, if there is no unfavorable weather, the crop will be very heavy."

The Frederick Examiner says: "We have never seen the crops so forward at this season of the year as they are at present. The wheat is fine and heavy. The prospect could not be more favorable."

The Frederick (Md.) Herald says: "The rain of last week has given an additional tinge to the deep verdure of our fertile farms. The prospect of a *wheat* crop has never been more flattering.

"We learn from a gentleman who has just returned from the western portion of the State, having passed through the greatest portions of Washington, Frederick, and Carroll counties, that the crops never looked finer, or promised a more abundant harvest. The rain of Wednesday was very general in those parts."

"A letter from Harford county, to a gentleman in this city, gives a good account of the crops in that vicinity. We learn also, from gentlemen who have recently visited the Eastern shore of Maryland, that the crops there are very promising."—*Baltimore Patriot.*

"If the weather continues as favorable as present appearances indicate, our farmers will be enabled to cut their crops about the middle of June."—*Catoctin (Frederick Co., Md.) Whig.*

"The Williamsport (Md.) Banner brings us the first complaint of the *wheat* crop we have yet had from any quarter. It says: 'We regret to state that in consequence of the continued drought the various species of grain in this county present a sickly and unpromising appearance. The smut, it is said, has made its appearance in the *wheat*, and the crop will be nothing like as abundant as formerly supposed.'"—*Baltimore Patriot.*

At a subsequent date, the Williamsport (Md.) Banner says: "The rains with which we have been visited during the past week have not been without their beneficial results. The *wheat* looks beautiful, giving promise of a copious harvest. The *wheat* in our county, (Talbot) since the passing of the drought, begins to look very promising and healthy. We have heard from a few farmers that the fly has commenced its destruction upon it; but as we have not heard it much spoken of, we are inclined to believe it is not

general. Should no disaster happen to it, we believe, notwithstanding the lengthy drought it has passed through, the harvest will be abundant."—*Easton (Md.) Gazette.*

"*Coldspring, Washington Co., Md., June* 2.—We have just had three severe frosts. The wheat appears to be in full bloom. No doubt the bloom is killed by the frost, and that the heads will be deprived of germination. Therefore, what we call in this country the *wheat* heads will be dropped. More than half will be destroyed should the germination be stopped on what is now in bloom."—*Baltimore Patriot.*

"Accounts from almost every section of the State concur in representing the wheat crops to be in excellent condition, and offering the promise of a full yield."—*Baltimore American.*

"A letter to the editor from Pipe creek, Carroll county, dated May 24th, says: 'I never saw the crops of *wheat* and rye appear finer than they do now in this whole section of country.' * * * *

"The Howard District Press says: Intelligence from all parts of the District represents the crops as in a flourishing condition."—*Baltimore Sun.*

In the months of June and July, during the harvest, the accounts continue to represent the crop to be a good one. Thus:

"In this State, also, the expectation of a good crop seems to be realized. The *wheat* harvest is already in progress. The Hagerstown Torchlight states that 'the wheat crops are uniformly good; and if they escape future damage, there cannot be a doubt but the yield will be greatly more abundant than any within the last eight or nine years.'"

The Kent News says: "The farmers have been generally engaged the present week in their wheat harvest. Our town has been dull, but we hope that good crops and 'good prices' may be realized by every one."

The Frederick (Md.) Herald of June 9, says: "Our crops of wheat and rye are all off, and a great portion of them already in the stack-yard and mow. The harvest is a heavy one, and its benefits will be felt by every class of our community."

"We see it stated in the Hagerstown Herald of Freedom, that the yield of wheat in Washington county will be a most bountiful one. Grain was cut in some parts of this county on the 11th instant, several days earlier than in any previous year.'

"The farmers of Carroll county, Maryland, have nearly finished cutting off their wheat crop. Indeed, many of them have finished housing it. Beyond doubt it is the largest crop ever before raised in the county, and the product will be double as much as it was last year."—*Carrolltonian.*

"Our farmers," says the Centreville Gazette, "have completed their wheat harvest, and, from all accounts, so fair a crop has not been cut for many years."

The following notice, however, somewhat conflicts with the last statement, though it refers to a different part of the Eastern shore:

"We see it stated in the Cambridge (Dorchester county) Chronicle, that in some fields the wheat is good, but on nearly all the light lands the Hessian fly has made some serious ravages, and in many instances rendered the crops totally worthless."

In Lyford's Price Current, under date of June 14, we find the opinion expressed that the wheat crop will be an average one. We give it, and the opinions of some other public journals, as we find them:

"The statements are very conflicting in regard to the forthcoming wheat crop. In some sections of the same State there are indications of a small crop, while others promise an abundant yield. We incline to the opinion, from what has been presented to us through the papers, that in the general there will be fully an average crop, if no injury is imparted to it before harvesting, as just previous to that operation lies the great danger of rust, arising from rains, immediately followed by a hot sun, which usually generates a humid atmosphere, while the heads of the grain are filling."—*Lyford's*, *Balt.*, *June* 14.

"The Baltimore American describes the weather to have been most delightful for harvesting, and the crop, it is believed on all hands, will be full as to quantity, and excellent in quality."

The Williamsport Banner says: "The harvest is now entirely gatherd in, and is one of the heaviest that has been cut for many years. The farmers state that, as to quantity and quality, it has rarely if ever been surpassed."

"Our Maryland exchanges bring us glowing accounts of the abundance of the crops, especially in wheat. In Queen Anne county the quantity and quality have rarely if ever been surpassed, while in Kent county a larger crop has been gathered than for many years."—*Baltimore Clipper*, *July* 15.

"The wheat crop of Maryland of the present year has not only been an abundant one as to quantity, but is likewise remarkable for the excellence of its quality. In the valley of the Susquehannah the products of numerous farms have been found to weigh sixty-eight pounds per bushel. In Frederick county, Maryland, the crop of one farm, recently sold to a miller, weighed sixty-eight to sixty-nine pounds per bushel."

On the whole, we believe that the crop was above an average one; therefore place it at an increase of 20 per cent. over that of 1844, which, it will be recollected, was a tolerable crop. Indeed, in the northeastern section of the State, some have placed the advance as high as one-third more.

The following notices of large yields have met our eye in connexion with the statements respecting the crop of wheat in Maryland:

"Mr. Joseph L. Huffer, near Catoctin, Maryland, for the purpose of testing his probable yield of wheat, threshed out fifty shocks, having 12 ordinary sheaves to the shock; and having measured it with his own hands, found it to produce the extraordinary amount of 41 bushels. Mr. Huffer's entire crop will turn out equally as well as the above parcel."

"Mr. Delashmutt, of Buckeystown, Frederick county, Maryland, delivered a load of wheat at the Monocacy mills, a few days ago, weighing sixty-nine pounds per bushel. It is believed that his whole crop will average sixty-eight and a half pounds per bushel!"

"In all contests for superiority in raising agricultural products, Carroll county is always a prominent, and most generally, a successful competitor. We lately published accounts of certain lots of wheat raised in Frederick county, that weighed sixty-eight and sixty-nine pounds to the bushel. The Carrolltonian states that some white wheat, the product of the farm of Mr. John Orndosl, of that county, was measured, and weighed seventy-nine pounds to the bushel."—*Baltimore Patriot.*

The wheat crop of North Carolina was more seriously injured. As early as in April, the Raleigh Register states: "The late drought has destroyed the *early wheat* in many sections of North Carolina, and much of it has

been either ploughed up or the cattle turned into it." The Norfolk Herald, Virginia, makes similar remarks respecting the crop in the neighboring counties of North Carolina, and says: "The crop is expected to be short." And in May, a letter from Chatham county, in the Raleigh Register, states: "We shall not have half a crop of wheat this year in this part of the country, caused by the cold and drought." Again: "A gentleman who is an extensive planter, residing a few miles from Edenton, North Carolina, commenced cutting his *wheat* on Thursday, the 22d May, being some weeks earlier than the usual time of harvesting. We are not informed, says the Edenton Journal, whether this gentleman's crop is a fair one or not, but we do know that the wheat crop generally, in this county at least, has been greatly injured by the cold and dry weather, and perhaps this may account for its ripening so soon." The drought in this State was most distressing; and, by accounts received since the harvest, the crop must have suffered most severely. In the central portion of the State, towards the west, the crop is supposed to have fallen off one half; and towards the east, not less than one fourth. In the northwestern section, it seems to have been somewhat better, and it is thought may have been about equal to the crop of 1844. On the whole, we think it must be not less a decrease than 15 to 20 per cent. We think it probable that in some sections, where considerable wheat was raised, this estimate may be considered too large; but allowing every thing favorable, in the warm weather, for the earlier ripening of the grain, we cannot form any more favorable conclusion.

The drought also, as already mentioned in our extracts under "*The Season*," most severely affected the State of South Carolina, and the wheat crop there felt its influence. As early as April, in the Edgefield Advertiser and Charleston Patriot, we find mention of frequent complaints and fears entertained respecting the harvest; and the wheat crop, it is said, is "seriously damaged," "a failure," "very sorry." Nor did the prospect improve in May. The Greenville Mountaineer, Cheraw Gazette, Columbian, South Carolinian, and Edgefield Advertiser, all agree in representing the injury to be great. They speak of it as "short of the usual yield;" "not more than two-thirds of the amount annually harvested;" "seriously damaged and suffering (also) from a black blast;" "will be cut short, if not entirely destroyed." It is probable, however, that in the upper part of the State, towards the west, the yield proved "better than was anticipated;" the grain, also, though "the stock" was "low" in the middle districts, proved to be "good." Taking the whole State through, the crop must have fallen very considerably. According to the information we have derived from correspondents since the harvest in the northwestern part of the State, where not much is raised, it was about equal to the crop of 1844. In the northeastern portion it may have been a little better—say "10 per cent." In the central section it is thought to have fallen "30 per cent." on account of the drought, and in the section west of this to have been at least 15 per cent. less. It was, probably, about 20 per cent. less for the whole State.

In Georgia, as early as the 25th of April, we find mention of the ravages of the Hessian fly in the counties near Milledgeville. Says the journal published there: "We learn that the *Hessian fly* is in the *wheat*, in several of the neighboring counties, and that their ravages have been dreadful. Whole fields have been totally destroyed by this troublesome insect, and others will yield not more than a fourth of what was confidently anticipated some weeks ago. We have been told that in an adjoining county,

a wealthy farmer, who always plants largely in wheat, found that one of his wheat fields was totally destroyed by them, while the adjoining field (the two being separated by a worm fence only) was untouched. It has been remarked, too, that in straight lines, across whose fields from ten to fifty yards apart, the destruction would be entire, while the balance would present a wholesome appearance."

The following are some of the subsequent notices in May, and on: "The wheat crop in this county is very promising; we heard a farmer say on Monday that he would commence reaping in ten days."—*Marietta* (*Cobb co., Ga.*) *Advocate*, 14*th May.*

"While complaints have been made of an extensive drought prevailing in some parts of this and the adjoining States, we have had a fine growing season. The wheat crop will be about an average one."—*Marietta* (*Cobb Co., Ga.*) *Helicon.*

"The *wheat* crops, with the dry weather, and heavy frosts which fell about the middle of March, have been measurably destroyed. Many farmers in Lumpkin, Union, and Habersham, will not make the seed which they planted last fall."—*Dahlonega* (*Ga.*) *Watchman*, 22*d inst.*

"With all the complaints of dry weather, crops look very fine in Lee, Thomas, and Baker. The wheat crop has far exceeded the most sanguine expectations of the oldest planters in this county."—*Sav. Georgian, June* 2.

The information respecting the northwestern section since the harvest is, that the crop is thought to have been "25 per cent." owing to the "increased culture" given to this product, and the "better yield." From the central counties west of the Ocmulgee river, the report is not as favorable, as it is judged to have fallen off at least "one fourth or one-third" from that of 1844. The crop, therefore, in the whole State, is believed to have been not less than 15 per cent. decrease.

In some portions of Alabama the wheat crop is about the same as in the previous year, while in other sections the early frost materially injured it; and the decrease is variously estimated from "10 per cent" to "one-third."

In portions of Mississippi some wheat is raised, but it forms so small a crop, comparatively, that it is difficult to form any very reliable estimate of the yield.

The same is the case with regard to Arkansas, where, as the crop in the early part of the season appeared promising, and from the scattered notices gathered, it seemed to be quite good, we have felt authorized to allow about the usual rate of increase for the average crops.

The crop of wheat in Tennessee, so far as we are able to ascertain, was a productive one. The West Tennessee Whig says, "the wheat crop in that region turned out to be very good." A similar report is also made in a public journal by a correspondent at Nashville. From other information, we learn that in the northwestern section of the State the crop was probably twenty per cent. more than in 1844, while in the northeastern it has been estimated as high as forty per cent. increase. We place the average increase for the State at about twenty per cent.

Although the drought was felt in parts of Kentucky, yet we believe the wheat crop was, on the whole, a good one. In April and May we find the following notices:

"During a short excursion into the country, a few days since, we were much gratified to see the wheat crops look so fine. Should the blighting rust not again visit it before its maturity, there will be an abundance, and to

spare, raised the present year for home consumption."—*Lexington (Ky.) Inquirer.*

"The *wheat* will generally turn out well."—*Maysville Eagle, May* 24.

In another journal it is stated, as from a gentleman who has lately travelled through Franklin, Woodford, Fayette, and Bourbon counties, that "the wheat crops look well, with a prospect of a very heavy harvest."

Again, in June or July: "It is the universal remark, that there never was grown in Kentucky a better wheat crop than the present. The frequent rains lately have somewhat retarded the harvesting, but we do not learn that they have caused serious damage to the crop. Kentucky has for years imported considerable quantities of wheat and flour; but it is generally believed that she will export a surplus from the present crop."—*Frankfort (Ky.) Commonwealth.*

Some accounts speak of the prospect in Kentucky as bad. The editor of the Shelby News, on the contrary, says: "In passing through a portion of the northern and northwestern sections of old Shelby, we were delighted with the fine appearance of the wheat crop."

The Knoxville Register, of July 30th, states that "the wheat crop this season is an excellent one, the quality of the grain produced being, as a general thing, superior to that of any crop for several years past. If the season continues propitious, the crop will be unusually large."

This, likewise, corresponds with the information otherwise obtained. Thus, in the counties east and northeast of the central it is stated that, "in 1844 there was almost a total failure; but in 1845, an uncommonly fine crop," which is rated even as high as "75 per cent." In the section lying northeast of the last, our informant says: "The warm weather was a great advantage to the wheat, and so good a crop has not been raised in this section for the last twenty years; which many think is owing to the cold dry spring and the fore part of the summer." He thinks the yield at least thirty per cent. greater. In the southeastern part of the State the crop was fully "equal to that of 1844," if not still larger. The crop, therefore, may fairly be estimated at twenty per cent. advance on that of 1844.

A species of wheat called the Reed-straw wheat is mentioned in the Louisville Journal, and the farmers of that region are advised to give it a trial. The ears are said to be "large and full, and the grains plump and heavy." This kind, also, it is stated, "ripens two weeks earlier than the common sorts, and therefore escapes the rust," to which they are liable. It weighs very heavy, and ripened last year by the first of June.

The wheat crop of Indiana has been a heavy one. The notices of its progress, in general, are highly favorable. It is true, mention is made of frosts, and apprehensions were felt in some parts of the State as early as April and May, but these were proved erroneous by the subsequent harvest."

A letter dated South Bend, St. Joseph county, Indiana, May 1, says: "I have recently travelled through the counties of Kosciusko, Elkhart, Marshall, St. Joseph, and Laporte, in this State, and have the gratification to say that we have never had a better prospect of an abundant crop of *wheat* than we have now. Last year our wheat was nearly destroyed by the fly; at present it appears entirely free from that and all other evils."

The Cambridge (Indiana) Reveille, the Lafayette Journal, and the Wabash Courier, all speak of the crops in their respective vicinities as very promising.

"*Indianapolis, May* 9.—From every portion of our State we learn that the *wheat* crop never promised more abundantly than at present. Should the present anticipations of our farmers be realized at the approaching harvest, prosperity will again begin to smile upon us."

"The weather is now warm and dry. The *wheat* crop looks at the present time remarkably well; and should the season continue to be favorable, we may expect an abundant harvest. We have not yet heard that the fly has made any appearance in this section of the country."—*Centreville, Indiana, May* 14.

"We are happy to have it in our power to say that the prospects for an abundant harvest never were better than at present in northern Indiana. The *wheat* crop especially, which is our greatest dependence, promises an unusual yield to the farmer."—*Laporte Whig.*

As the harvest advanced, the statements are equally decisive. Thus, in June and July, the Goshen Democrat says, that "the wheat crop in northern Indiana has not been better during our residence in the State. It will nearly all be harvested and secured during the present week in good order. Elkhart county alone will have a large surplus for the eastern market. Some of our wheat fields average 30 and 35 bushels to the acre, and 20 bushels are a common yield."

"Wheat comes in briskly and finds a ready market; Pulaski, Fulton, Miami, White, Carroll, and Cass, have an immense surplus, of which between 250,000 and 300,000 bushels will probably find its way to this market. Such a time of almost universal prosperity among farmers was never before known in this part of the country." "We have no means of arriving at a correct estimate of the quantity, but those who know say it will be as large as was ever known before, if not larger."—*Logansport (Indiana) Pharos.*

"The Lafayette Standard of the 18th says: "Several lots of new wheat have already been sold in this market, at prices ranging from 62 to 65 cents. It is immensely heavy, and a most excellent article. The crops in this region will be most abundant—far exceeding in quantity and quality those of any previous year."—*July* 26.

From other informants, we are told that in the upper central counties, above the Wabash river and northwestern part of the State, the crop is thought to be double what it was the previous year, while by yet another person it is estimated at much more than double. Of the southeastern section, bordering on Ohio and the Ohio river, it is likewise estimated to be an advance of 100 per cent.; and it is stated that "the crop of last year was severely affected by the rust, but this year there was no rust or any thing scarcely to damage the crop. In the county of Dearborn, there was some damage by the *weevil*, but no general appearance of it. In the central section it is estimated to have gained "25 per cent," and in the southwestern "50 per cent," on the crop of 1844. Of the former part it is mentioned as a cause, that there was "increased industry, stimulated by the prospect of a market, and an increased quantity of land reclaimed from the forest state." Another informant, whose opportunities of information are better than usual, also speaks of the great increase of the crop throughout the State; and we feel authorized, by all we can learn, to fix it at "30 per cent."

A similar advance may be given, we believe, to the wheat crop of Illinois. It will be recollected that, in 1844, both this State and Indiana suffered severely from incessant and heavy rain, which destroyed large and fine crops

in prospect. The crop of 1845, though suffering somewhat in sections from drought, yet has had, on the whole, a very propitious season for growth and gathering. We give such notices of its progress as we have met with:

April 23d, the Chicago Democrat says: "The wheat crop looks favorable. All that is now feared is dry weather." Yet later: "The *wheat*, in general, looks tolerably well only; on some farms it stands thin upon the ground—probably in consequence of the extreme dry weather last fall, when it was sown."—*Quincy Whig, May* 7.

"We have made a short excursion into the country, and find the wheat crop in a very fine condition."—*Chicago (Ill.) Farmer, May.*

The Alton (Ill.) Telegraph says, that "the wheat in that vicinity looks well." So, in June, the Quincy Whig says: "From all parts of the country we have most promising accounts of the crops. The prospect of wheat is very fair; the stalk is not as thrifty as last year, but heads fill out well, and the grains are large."

"We have had several good showers of rain the present week. The corn and *wheat* in this vicinity begin to 'look up,' though a portion of these crops was entirely destroyed by the frost."—*Springfield Republican, June* 6.

In the Chicago Democrat, of the 10th June, we find the following: "The growing *wheat* still promises well, although, from the want of rain in the southern sections, the straw is light and the head uncommonly short."

Again: "Advices from western Illinois represent the *wheat* crop as very good. Although the stalks are not as luxuriant as usual, the heads are heavy and full."

"From present appearances," says the Warsaw Signal, "the crops in this section of the country promise to be unusually large. The season thus far has been favorable."

The editor of the Prairie Farmer, for June, says: "In our travels through southern Wisconsin, northern Illinois, and the Military tract, we have observed the *wheat* looks pretty well. The winter, that was late sown, is thin on the ground, and also the late sown spring, owing to the dry weather succeeding the sowings. But should the season be favorable, this will head out larger, and many fields will yield more bushels of wheat than that growing thicker. The straw is almost universally very short. The fly has done more or less injury all over the State, and it has become a permanent enemy to the prairie farmer."

Again, from the New York News: "The Alton Telegraph says: 'A field of wheat on Scaritt's prairie, in this county, was harvested on the 13th of this month, (June.) This is the earliest we have ever known grain in this country to be fit for the sickle.'"

"*Marseilles, Illinois, June* 25.—The weather, from being cold and dry, is now hot and sufficiently wet. *Wheat* looks well, and is fast ripening. One week more of good weather will insure a good crop."

"A gentleman who lately passed through the Rock river country informs us that the wheat crop never looked more promising. The quantity grown this season in northern Illinois will far exceed that of any former year."—*Albany Citizen.*

Again, in the Prairie Farmer of July: "Having just arrived at Springfield (23d June) from Chicago, passing through Du Page, Kendall, La Salle, Putnam, Woodford, Tazewell, Logan, Menard, and Sangamon counties we send a word of our own observations concerning the crops. The prospects now are, there will be an abundant yield of grain of all kinds. I

the four southern counties we saw numerous what fields that will be ready for the sickle this week, and we learn some were cutting in this county last week. Ten days of good weather insures a large crop through all this region, though the late rains, continuing for about ten days, have saturated the earth, and there is considerable danger of rust in consequence. A few hours of hot damp weather would ruin thousands of acres, that now promise twelve to twenty bushels. South of this, we learn they have harvested a good crop. We saw no wheat fields injured by the frost, or lodged, though we have been told there were some."

"Many of the farmers in this section of country last week commenced cutting their winter wheat, and immense quantities will be cut this week. We are pleased to hear, from every direction around us, that there has never been a finer crop. It is a common remark of every one that goes into the country, or that comes to town from the country, when speaking of the crops, 'I have never seen such wheat.' This is highly encouraging to our people, and must cheer up many an agriculturist whose crop had failed the last year or two."—*Peoria (Illinois) Press.*

"Our farmers generally, by this time, have harvested their *wheat*. The weather for the last three days of the week was quite favorable for harvesting, and the whole crop has been secured in good order. The yield is fully equal to the most sanguine expectations of the farmer, and the quality of the grain is very superior."—*Quincy Whig, July* 9.

Still later in July, the Springfield (Illinois) Journal of the 18th says: "Within a few days past, there have been heavy rains in this region of country. *Wheat* will turn out better than was anticipated."

"A traveller informs the editor of the Commercial Advertiser, Buffalo, that in Illinois he saw 40,000 acres of *wheat* in one body, divided only by cross-roads. The yield on the whole lot gave promise of something better than was seen last year."

"Since our last publication, the weather, although intensely hot, has been generally favorable to the harvest. The *wheat* is all saved, and will, it is believed, be of the very best quality; a small part only having been injured by the late rains."—*Alton Telegraph.*

Our information from other sources corresponds with the above, and is all favorable. In the section embraced from Peoria county to Jersey county, along the west side of the Illinois to the Mississippi, being the central western tier of counties, it is estimated that the increase above the crop of 1844 is equal to "50 per cent." "The last year the crops were bad; this year, fine." In the southeastern part, bordering on the Ohio and Wabash rivers, the yield is thought to have been "10 per cent. better;" in the southwestern, bordering on the Mississippi, "25 per cent. increase;" and in the northern, and along Lake Michigan, also, "25 per cent. more." We put the estimate for the whole State at 35 to 40 per cent. increase. Some have placed it much higher; but we are aware how liable all are to place their estimates too high.

One writer in a public journal says: "It is estimated that Illinois alone will furnish a surplus of 8,000,000 bushels of wheat this season. An advance of only ten cents per bushel would more than pay the whole interest on her debt; and it has already advanced more than twenty."

We cannot agree with this view, if it is meant by it that the whole of this amount is raised by this State, as it would make the Illinois crop as much as 16,000,000 of bushels. The crop of 1839, according to the census, was

but a little over 3,000,000; and the variations of the crop have been large since then. The crop of 1842, (which was a fine crop,) according to the best estimate we could gather, was only about 5,700,000; and in 1843 and 1844 it was much reduced. The crop of 1845 was a very fine one—probably above one third more than in 1844.

An agricultural journal says: "We learn that 30 bushels to the acre is no uncommon crop this year through the north of this State, and we presume that the same is the fact in sections adjacent."—*Prairie Farmer, August.*

It will be recollected that the wheat crop of Missouri, in 1844, was greatly injured. The accounts for the year 1845 are much more favorable. In May we find them as follows:

"In the counties of St. Charles, Warren, and Montgomery, the crops of *wheat* are well set, and in a flourishing condition; the growth was a little retarded by the dry weather of the spring, but the recent rains have given it fresh life; and should the season continue to be favorable, very fine crops may be expected." "The present prospect for an abundant *wheat* crop upon the Illinois and upper Mississippi is said to be flattering."—*St. Louis New Era, May* 5.

"*Crops.*—From present appearances, we are told that the crops of *wheat* and corn on the upper Mississippi and Illinois promise an abundant harvest. The *wheat*, although retarded somewhat in its growth by the dry weather, in the early part of the growing season, has been brought out by the late rains, and looks fine, and promises to do well."—*St. Louis New Era, May* 20.

"Extract from a private letter to one of the editors, written from the southwestern corner of Missouri: 'The prospect for *wheat* in this country is very favorable. I hear all the farmers say they have never seen more wheat growing, or look better; and if their expectations should be realized, and not marred, there will be sufficient flour manufactured here to supply all the Arkansas river district.'"—*Van Buren* (*Arkansas*) *Intelligencer, May* 24.

In June, some apprehensions seem to be entertained of rust from the rain. A correspondent of the St. Louis Republican, writing from Warsaw, Missouri, says: "The wheat crop in the southwest part of the State is very short, and everywhere uneven; most of it is not half the usual height."

The Republican adds: "We have similar reports from other parts of this State."

The St. Louis New Era says: "The rains of late have been frequent and heavy, and will give a very desirable impetus to the general growth of vegetation. It is feared by some that the *wheat* crop may be injured by the rust in consequence of the continued wet weather."

"We begin to despair of the *wheat* crops, (says the St. Louis Republican, of the 27th ultimo.) It has rained more or less for the last fifteen days; and as yet there is no prospect of settled clear weather. The crop of *wheat*, which, until the commencement of the rain, promised an abundant yield, is greatly injured, and must soon be wholly destroyed, unless a change in the weather takes place. That which was cut just before the rain is, of course, lost. This will be a sad blow to our farmers, and must sensibly affect all other branches of business and trade."

Still later, and in July, the St. Louis Republican says: "In our own State the only apprehension seems to be, that the heavy rains of the last week may prove injurious to the wheat, which is ready for harvesting, and a small

portion of which has already been cut. A few days of dry and not too warm weather will place it out of danger."

"The last few days of dry weather have enabled the farmers to harvest their wheat; and it is free of rust, which was much feared."—*St. Louis Republican, July* 2.

Again, from the same paper: "The yield of *wheat* will probably exceed that of any previous year."

In the New York Farmer, it is said: "A letter from Gallatin, (Mo.,) as early as July 6, says: 'The harvest is just over; the *wheat* is excellent.'"

The Fulton (Mo.) Telegraph also says: "The *wheat* crop, from present appearance, will be more than an average; and, in another journal, speaking of Jackson county, it is said: "The *wheat* crop has been harvested, and is more abundant than usual."

Subsequent to the harvest, the following statement is also made in the St. Louis New Era: "The new crop has just commenced arriving freely; and, should the upper streams continue even in their present difficult stage for navigation, we may expect to see, in the course of three or four weeks, large quantities of wheat pouring into the market; even at this early period, there are thousands of bushels of the new crop lying at the landings along the Illinois, upper Mississippi, and Missouri, waiting shipment. All the boats which have reached this port from above, for three or four days past, have come down with as much as they could possibly get along with; and many of them, particularly those from the Missouri and Illinois, had to refuse more wheat than would have loaded them twice over in a fair stage of water. The *wheat* harvest has, indeed, been a magnificent one. From every quarter the cry is, *plenty;* on the Missouri, upper Mississippi, and Illinois, the average yield over the crop of last year will be full 33 per cent.; and, in many sections of the county, full 50 per cent.; add to this the superior quality of the grain, which appears to be uniformly of nearly the same quality, and there must be a great surplus. How, when, and where it is to be disposed of, remains to be seen."

From the above accounts, we believe we may fairly place it at one-third more than the previous year, in which, as it will be remembered, it suffered so largely.

From none of the large wheat growing States do we receive more encouraging accounts of this crop than from Michigan. Indeed, its whole progress seems to have been unusually good. The year 1844, it will be remembered, was a great contrast to this, and that the crop suffered most severely from the rust. We give the history of the crop as we have gathered it, commencing with March. The weather was cold and backward, but it is said "our great staple never looked better at this season of the year, and there is every prospect that the labor of the husbandman will be as favorably rewarded as could be desired."

In April, the Marshall Exponent says: "There never was a fairer prospect of a good wheat crop than there is at the present time. We have inquired of farmers in almost every town in the county, and get the same answer: 'it looks well—never better.' No insect has made its appearance yet, and the grain may now be considered secure from that danger. We rejoice to learn from our exchanges that crops look equally well in every part of the State."

Again: *Oakland county, Michigan.*—The editor of the Oakland Gazette says: "While jaunting through the middle and northern parts of this

county on the 12th inst., we observed that the *wheat crop* appeared better at this season than it has for many years past. The prospect is fair for a very large crop; and, with dispensations which a Divine Providence alone can bestow, we think there will be more wheat produced in those portions of the county the current year, than at any previous year since its settlement."

So, in May: "The *wheat* crop never looked better in this region, at this season of the year, than at present. There are some fields this side of the county house—we believe on Judge Thompson's farm—that are well worth a journey from the village to behold."—*Adrian* (*Mich.*) *Expositor.*

"In this section the *wheat* is growing very rapidly; too much so, it is feared by some."—*Marshall* (*Mich.*) *Expounder.*

"The wheat fields (except in that part of the country visited by hail storms) present a glorious appearance; and unless some accident should happen to it before harvest, the crop will be immense. We hear no complaint of the ravages of the fly this year, as we did last."—*St. Joseph* (*Mich.*) *Advertiser.*

"The prospects of the *wheat* crop in Michigan, as our advices prove from all parts of the State, were never better than at present. Even on land heretofore considered almost barren, our wheat appears exceedingly rank, and nothing short of an uncommon drought can now destroy it."—*Jackson Gazette.*

Kalamazoo, Michigan, May 16.—*Wheat.*—"Never since our residence in the country have we seen the promise for a heavy wheat crop as good as it is now. Not a poor piece have we seen yet. If nothing should happen to it before harvest, all complaints of hard times, scarcity of money, &c., will be at an end. Our prairies challenge the west."—*Telegraph.*

"The *wheat* in this part of the country looks well. We have never seen it better; and we hear similar accounts from most parts of the State."—*Ann Arbor* (*Mich.*) *Journal.*

Correspondence of Livingston and Wells's express, No. 10, *Wall street.*—"*Shiawassee, Michigan, May* 19, 1845.—The *wheat* crop promises fair, and I am told there is at least one third more *wheat* on the ground this season, than there was last."

In June: "From all parts of the State, with few exceptions, we hear the most encouraging accounts respecting the prospects of the incoming crops. This is peculiarly gratifying at this time to the farmers of Michigan. Last year the wheat crop in this State was very small, while our neighbors in Ohio, Indiana, and Illinois, reaped an average harvest."—*Ann Arbor Argus.*

Again: "*Ann Arbor, Michigan.*—The crops, after all, look well, especially the *wheat.* The spring crops were mostly cut down, and in some cases twice or thrice; but the fine growing weather since has restored them. The farmer's prospects are good and promising."

A farmer from the country informs us "that fears are entertained that the late frosts have ruined the prospects of a good wheat crop."—*Detroit Free Press, June* 2.

At a later date, the Detroit Advertiser says: "We learn from various sources that the *wheat* crop has not probably suffered materially, or at least generally, in this State, from the late frosts. But the drought has sensibly affected it in several places." The Jackson Gazette, and the Coldwater Sentinel, respectively, after alluding to the drought and frosts, speak of the

wheat as "uninjured," and affording promise of an excellent harvest. The editor of the Michigan Farmer, under date of 15th June, says: "From every quarter we hear the most encouraging accounts of the condition of the *wheat* crop. The papers of every section of this State unite in the anticipation of an abundant harvest. The wheat insect appears nearly to have intermitted its ravages. The crop emerged perfectly unhurt from a changeable, snowless winter; and, since the opening of spring, with the exception of one or two seasons of drought—which, however, has not been very severe—the progress of the crop has been of the most promising description."

In the month of July, and during the harvest, the accounts still continue to be cheering, like the following:

"We are informed by a gentleman, direct from Michigan, that the wheat crop in that State is better than ever before known. It will be mostly harvested this week, and will, therefore, be housed in good condition, as the weather is warm and dry."—*Albany Argus.*

"The *wheat* crop in this State is said to be nearly double in quantity that of any previous year." "The Detroit Free Press of the 16th instant, gives the following account of the harvest in that State: "In Michigan, we are able to say, so far as we have heard, the *wheat* crop was never better in quality, or larger in quantity. The farmers in the western portion of the State are already in the midst of the harvest; and in all parts they will commence in the course of this week and next. We shall have a large amount for exportation." "The harvest has commenced in this section of the State," says the Marshall Expositor, "and the crop is coming in nobly. It will be the best wheat crop ever harvested in this country. We have heard the average estimated at 25 bushels per acre; but this is probably too high. Last year the average was said not to have exceeded seven bushels per acre. The berry is said to be plumper and the wheat heavier than in any former year." "Some farmers have commenced harvesting their wheat, and the crop will quickly be in market. The straw is rather short, but the ear well filled, the berry plump, and the crop will be full an average one. The surplus in Michigan will probably be twice as great as last year." "The farmers of Michigan are now in the midst of their wheat harvest, and we are happy to say that it bids fair to prove the richest harvest ever gathered in Michigan."—*Detroit News.*

"A friend of ours, who is a practical farmer, and, we may add, a member of Congress, has just called on us on his return from Michigan, having travelled in that State in various directions, and having had an excellent opportunity to inspect the crops. He says the crop of wheat was never so good or abundant as it is this year. As an evidence of it, a large portion of the wheat will weigh sixty-five pounds a bushel, and the product will be one third greater than the largest crops ever raised in that fertile State. The above authority may be implicitly relied on."—*New York paper.*

The Grand Rapids Inquirer says, that "in the county of Ionia, in Michigan, there are this season over 20,000 acres of *wheat*, all in first rate order, furnishing assurances of a large crop."—*June.*

The accounts from Michigan are of the most encouraging kind. A letter in the Detroit Advertiser, dated Pontiac, Michigan, August 11, says: "If the accounts are anything like correct, the quantity of *wheat* raised in this section of country alone must be prodigious. In the town of Washington, Macomb county, I am told it is nothing remarkable for one farmer

to thresh his two thousand bushels of wheat; and one man, I am assured, has nearer five than three thousand bushels. I saw a farmer from the border of Lapeer, who told me he was only 'a young beginner,' but reckoned upon his one thousand bushels of wheat, at least, this season—some of his land bringing him as much as forty bushels to the acre."

The American Agriculturist for November last gives a letter from a correspondent, which contains the following remarks respecting the wheat crop of Michigan:

"Wheat is the great product of the State; and on this the farmers principally rely for their available exports. Never did their efforts receive a greater reward than the present season. The estimate of several judicious citizens is, that the crop fully averaged 20 bushels per acre over the State. I was informed of a wheat field containing 100 acres, which averaged over 45 bushels per acre, and one measured acre of which produced over 60 bushels. A cargo of this year's crop, from Michigan, averaged one barrel of the best superfine flour for every 244½ lbs. of wheat."

"*Great yield.*—Henry Jones, of Young's prairie, Cass county, raised on one acre of ground, this year, *sixty-one bushels* and *twenty-five pounds* of wheat. This is the largest yield we have heard of in western Michigan. A large number of fields in this section have yielded from 30 to 45 bushels to the acre this season. Perhaps the world cannot furnish a finer or more productive country for grain than the St. Joseph valley. When we cast an eye back to the land of our nativity, where, eighteen years since, we followed the plough, among the rocks and stones of Connecticut, where 15 bushels of rye to the acre was considered a fair yield, we cannot but wonder how mortal man can be content with such an abode, when the rich and fertile soil of the west holds out inducement the most inviting to all."—*Niles Republican.*

From other sources of information we also learn that in Oakland county the wheat crop is the "largest they ever had." In Ionia and Berrien "unusually large;" as a specimen of which, it is stated one farmer has 106 acres which will average "30 bushels to the acre;" and, of the whole State, "more wheat will be harvested than for three preceding years." In the southwestern quarter of the State, bordering on the lake and on Indiana, the estimate is "50 per cent. more." The fly and wet weather injured it in 1844; in 1845 it was, in all respects, favorable. In the central eastern section, lying on the boundary line, it is likewise estimated at "50 per cent. more."

Another informant in the southeastern section says: "Three times more than in 1844." The editor of the Michigan Farmer says: "The returns from different counties vary from 25 to 40 per cent. In one county only, from rust, the falling off is said to have been 75 per cent.; never so beautiful a yield; scarce a bushel is brought to market that does not considerably overrun in weight, and the flour produced from it is of superior excellence." He thinks the amount to be more than double the former year. We have, however, after full consideration, fixed it about 75 per cent. more. This we have done in view of the increase, not merely from the more favorable season, but of the lands newly brought under cultivation, &c.

A new insect in that section is mentioned in one of the public journals, as follows:

"The Michigan Farmer notices a new wheat insect found preying upon the wheat in that State, and which is described as follows: It is the product of a small greenish fly, about three sixteenths of an inch in length.

The larva is a white worm, one-fourth of an inch long, ribbed, without feet, with two forked black lines on its forehead, and in some cases a streak of light green extending lengthwise. The worm is found in the straw just above the upper joint, where it devours the juices which would otherwise ascend to the head. The heads of wheat denote its presence by turning white prematurely, when the grain is in the milk. In one instance nine eggs were found in a single straw; one of which had just hatched. Have any of our readers seen any such insect?"

The increase of Iowa and Wisconsin, by the influx of population within the past year, is said to be great, and due allowance must, no doubt, be made for the additional quantity of land brought under cultivation. Besides this, their crops of wheat were evidently much greater than in the year 1844. As early as May, the prospect is represented as "promising a very heavy yield." The Bloomington Herald speaks thus, also, of the crops of Linn, Cedar, Muskatine, Washington, and other portions of Iowa, which "bid fair to yield an abundant harvest." The Lee County (Fort Madison, I. T.) Democrat of the 17th instant, says: "We have conversed with many of our farmers during the present week upon this subject, and have been assured by all of them that grain of all kinds looks remarkably fine, and promises an abundant harvest. Many of them say that for several years past they have not seen crops look so promising as they do at this time."

As the harvest approaches, and subsequently, we are furnished with the following notices of the crop: "The Miner's Express of the 4th of June, published at Dubuque, Iowa, says: 'The crops in our Territory generally present a most promising appearance. The prospect of the *wheat* crop is especially flattering. It is estimated that there will be more wheat harvested in Iowa this season than during the two preceding years.'"

Iowa.—The reports from this section of country are very flattering. The *wheat* crop is very promising, with every indication of an abundant harvest. The crop of *wheat* has been gathered, and the Bloomington Herald says: "A crop full one-third larger than usual will soon be in market, and we learn that some of our merchants are making contracts at fifty-six cents per bushel. We are further informed that the article is considerably superior to that of last year's production." Since the harvest, also, we learn from one well qualified to judge, that the crop was much larger than that of the preceding year, as "more land was tilled by the old settlers; the increase of population was greater than previously known; the season was more favorable; the produce per acre more, and the quality much better—in the last two particulars, better than for eight years." We believe that the advance was not less than one-quarter, or perhaps one-third. Mention is made of a new insect, which, it seems, is doing great injury to the wheat crop sown for 1846. The following is the account to which we allude:

"*Destruction of wheat.*—By a letter received by a gentleman in this city from Col. G. M. Kinkle, of Buffalo, Iowa, dated October 23, 1845, we learn of the appearance of a curious insect, which is doing great damage to the wheat. He says: 'Notwithstanding the luxurious harvest of this season, there is every appearance of a severe pestilence of a curious kind here. About the 1st of September there was a singular kind of insect made its appearance in most of the farms over the country. Its first appearance is a small black bug on the surface of the ground, and on some farms the surface for some inches deep would seem to be alive with them. Some farmers, who have sandy land, say it seemed as though every grain of sand was

becoming alive. In a few days after their first appearance they climb upon the corn, wheat, or whatever green thing is in their way, and then turn into a small fly about half the size of a house-fly, and suck the substance from the stalk of the grain until it withers away. Many crops of fine winter wheat, which came up and looked prosperous, have been entirely destroyed by them, so that the farmer has been compelled to sow it over again. The curiosity of it is, no one ever saw such a bug or fly before. It baffles the ingenuity of all to tell what it means. Nothwithstanding we have a frost every night, and have had some hard freezes, yet, as soon as the sun is up and warms them, they go to their work of destruction again. They not only eat the young wheat above ground, but kill it at the roots. If they increase another season as they have this, they will sweep every thing before them.' "—*Philadelphia Ledger.*

The following notices give us some idea of the state of the crop in its progress in Wisconsin:

Extract from a letter dated Troy, Walworth county, Wis., March 13, 1845: "The *wheat* crops throughout this region present a most promising appearance; and, if no accident happens, we shall send an increased quantity to the eastern market the coming season. More ground has been sown in this, and the adjoining counties, than in any preceding year. I think Walworth alone will spare from 100,000 to 150,000 bushels. Emigrants are fast pouring into the Territory; but as the government land which is of any worth is all taken in this section, the tide is turning northward and more westerly. We have had fine spring weather for the past few weeks, and everything indicates an early opening of the farming season with us." (Troy is about 30 miles S. or S. W. of Milwaukie, and about the same distance N. W. of Racine.) In May also: "The growing wheat never promised fairer at this season of the year than it now does. It has a very luxuriant growth. It is believed the crop is out of the way of the *fly* and other insects; and there is now the fairest kind of a prospect of an early harvest and an abundant yield. It is calculated that at least three-eighths more land is in wheat this year than last; so that it is a tolerably safe calculation to estimate the export of wheat from Wisconsin of the growth of 1845, at 400,000 bushels."—*Racine Advertiser, May* 20.

"It is stated in the Platteville (Wisconsin) American of 2d instant, that the army worm is committing great ravages on Major Rountree's meadow, and on other farms in that county, where they have done considerable damage to the *wheat crop*. We have not heard of this army worm's having invaded either the *wheat* or grass fields in Racine, Walworth, or Rock counties."—*Racine Advertiser.*

From all parts of the Territory we learn that the *wheat* looks finely. "Never, (says the last Milwaukie Sentinel,) it is said, was there a fairer prospect for a large crop of *wheat*, than there is the present season."

"From all parts of the Territory we learn that the *wheat* crop looks fine, notwithstanding the open winter, and seemingly unfavorable weather until the opening of spring. Wisconsin is the surest wheat country in the world." *Milwaukie Courier.*

So, in June: "In Wisconsin the wheat crop is said to be uncommonly fine. The impression we receive from the various accounts which reach us is, that, in the country at large, the wheat crop is not likely to be an average one; though, taking into account the large quantity that remains

over from last year, there can be no lack. In dry sasons, the stalks yield more seed in proportion to the straw than in wet ones."

"*Milwaukie, June* 25.—The recent showers we have been favored with throughout the Territory were as beneficial as they were acceptable, and have advanced the crops one-third, and our farmers predict that they will have a better crop by one-half than ever before. Wheat at present averages six feet in the fields."

And yet later still: "The Wisconsin reapers are in the field gathering in as good a crop of *winter wheat* as was ever produced in the Territory. One-third, if not one-half more ground has been sown this year in wheat than in any former year; and the yield will be at least as good as at any previous period. The *spring wheat*, which of course ripens some two or three weeks later than the winter grain, also promises to yield an abundant crop."—*Racine Advertiser, July* 15.

"The editor of the Green Bay Republican makes a favorable report, from personal observation, of the crops in northern Wisconsin, in the upper country, bordering on the Fox river valley. *Wheat*, corn, oats, and barley are better than ever before. The *wheat* is heavy and free from smut."

"It is stated by the papers in the Territory, that the last harvest has been the largest and most productive one to the farmer that has ever been gathered in the country. The surplus wheat raised will amount to an immense quantity—Rock Island county having over half a million bushels surplus, and Walworth county an equally large yield. The prospects for next year are still more flattering; double the amount of wheat has been sown this fall that there was the last; and, as the weather so far has been unusually propitious, the young grain throughout the Territory has the best possible appearance. From the quantity of new land broken up and sown in Rock county, it is estimated that the surplus yield in that county alone next year will amount to one million of bushels."

The following is from the Tribune of September 10th: "We have often heard of the prolific crops of wheat in Wisconsin, and the facility with which settlers are reimbursing their original outlay, but the following from the Racine Advertiser goes ahead of all previous operations. It says that two farmers from Jamesville, in Rock county, whose farms adjoin, last fall had conjointly 200 acres of prairie broken and sown in wheat; the work being performed by two young men, with ten yoke of oxen, and two boys to drive, in a few weeks. These 200 acres of wheat have recently been cut by means of a machine, occupying only 12½ days, with an extra expense of fifty cents an acre for binding and stacking. The wheat turned out an aggregate of 5,000 bushels, worth $2,500, or an average of 25 bushels to the acre. On Friday the owner came to Racine with two wagons loaded with an aggregate of 205 bushels of wheat, which he sold to Mr. Richmond at 62½ cents the bushel."

The following is from the Tribune of September 15th, in a letter dated Dubuque, September 1st: "The crops in the Territory are unusually fine. *Wheat* has never been equalled in 'the memory of the oldest inhabitant.' The increase of the wheat crop of Wisconsin may therefore be rated as high as that of Iowa."

The wheat crop of New England, being raised in small fields, and not properly a staple to any of these States, is, on this account, estimated with more difficulty than in those States where it necessarily attracts more attention. In the more northern sections, the varieties of spring wheat are

the principal ones the culture of which is attempted. The weevil and the worm are the subject of complaint in Maine; and, owing to the ravages of the former insect for some years past, the farmers have been so much discouraged as to discontinue raising this crop. The Maine Farmer states that the crops in Piscataquis county "will not turn out so well as was anticipated. The wheat crop has suffered much from the ravages of the weevil—to such an extent, in fact, that many farmers have not considered it worth harvesting, and, consequently, have mowed down entire fields of it, curing the same for foddering purposes."

The Bangor Whig says, that "the wheat crop in that vicinity is much injured, and many fields ruined by the weevil and rust."

In some parts it is thought to have been ten per cent. better. As the crop of last year (1844) was better than ordinary, we believe that a deduction of five per cent. must be made for this year's crop. The same was probably the case in New Hampshire.

In Vermont, we are told that, while in some parts of the State the drought seriously affected the crop, so that it fell off probably twenty-five per cent., yet, taking the whole State, there was probably an average crop, which would be an increase of about ten per cent. on the previous year. One informant writes: "Wheat, in 1844, was best at the north, while at the south it was less in quantity and meaner in quality; in 1845, it is best at the south; and as the population is mostly at the south, there can be no doubt that ten per cent. more than last year is not a high estimate." We believe this to be a correct conclusion, and have accordingly, as it corresponds with what we can learn respecting the general crop of the State, placed it at ten per cent. increase on the crop of 1844. Complaints of the weevil are likewise made. In the lower part of the State there has been some improvement, however, in the culture, and the grain of Windham county is estimated at thirty per cent. more. This is attributed to the application of lime and ashes, and the selection of soils which contain magnesian limestone, by which tolerable crops have been secured.

From the Boston Cultivator, also, we learn that the wheat crops are "uncommonly large and fine in the vicinity of Burlington"—while, in the Maine Farmer we are informed that the crop has "come in well," and there is an "abundance of wheat." In the northeastern part of the State, however, owing to the ravages of the weevil, it is thought to have fallen off considerably. Taking the State through, we suppose it may be considered at about ten per cent. gain on the crop of 1844.

The wheat crop of Massachusetts, it is believed, was a small gain. In the upper middle section of the State the yield is variously estimated in different towns at from "ten to twenty-five and thirty per cent. more." In the southern corresponding section, at "five per cent. less." In the western part of the State, "twenty-five per cent. more." A good judge residing there says: "The wheat crop, as compared with that of 1844, is one-fourth more, and we attribute it, in a great measure, to the favorable spring months. The weather not being very warm, and a suitable quantity of rain, winter wheat came forward with great rapidity, and, without a check, ripened for the harvest. Spring wheat (which is the greater crop) was early sowed, in consequence of the ground being ready for the plough much sooner than usual. Notwithstanding that some few pieces were affected by the drought, we have had a better crop than for many years previous, and the insect worked much less than years before." In view of the statements respect-

ing the crop, therefore, we place it at an increase of fifteen per cent. on that of 1844.

The crops of Rhode Island and Connecticut seem to have been very similar with those of the adjoining States. In the former, it was probably about ten per cent. more, and in the latter about fifteen per cent. advance on the crop of 1844. In the Albany Cultivator for November last, Mr. Claudius Allen, of Cheshire, Connecticut, writes respecting wheat as follows:

"To encourage the farmers throughout New England to sow more *wheat*, I can state that there has been more or less of wheat sowed on my farm for forty-five years, and there have been but two or three years, at most, when there has not been a pretty fair crop. In 1836 or '37, when there was a great scarcity of wheat throughout all the States, there was here an entire failure. On about four acres, I did not receive my seed sown that year. Since then the crops have been very good. For fifteen years that I have owned the farm, there has no insect of any kind injured the crop at all, that I am aware of. This year's crop is superb, weighing 62 pounds to the bushel, and very plump. I generally soak my seed in strong brine, made of common salt, with saltpetre, ten or twelve hours; then mix with slacked lime or plaster of Paris. This season I have sown on seven acres ten bushels of seed, raised near Seneca lake, New York. I generally change my seed once in three or four years."

The State of New Jersey raises considerable wheat, and the last crop was much better than that of the preceding year. The notices given during the harvest, and the information since received, authorize the advance of 15 or 20 per cent. on the crop of 1844, which was less than an average one. Thus—

The Salem Messenger says: "During the last week our farmers were in the midst of harvest. The golden grain, which a few days since was waving far and wide over many a field, has bowed its head to the sickle of the merry harvester, and been gathered into the barns of the husbandman. Scarce any one complains of a short wheat crop."

The Somerville (N. J.) Whig says: "Last week some of our farmers were in the midst of their harvest, and had a few favorable days in which to gather it. Grain has a clean and plump appearance, and the yield is generally good."

In the central counties, stretching across the State, the crop is said to have been full an average one. Further north, it is estimated to have been 25 per cent. more; as more was sown, and it was not affected by the rust or fly.

Similar was the condition of the crop in Delaware. As early as May, it is stated, in the Wilmington Journal, that "the prospect of an abundant wheat crop was never so flattering;" and this promise seems to have been fully realized, and the grain was harvested in fine order, and above an average crop. There was doubtless at least 20 per cent. more than in the previous year.

We notice in an agricultural paper the following statement respecting a fine yield of wheat: "Edward T. Bellah, esq., of Brandywine hundred, Delaware, harvested the past season 358¾ bushels wheat from 9 acres, being 39¾ bushels to the acre. He manured the field in the spring, planted corn, cut off the corn, sowed it in wheat, and fluked it in both ways among the corn roots, and gave it no other dressing except to sow 39 bushels bone dust over one acre, which he did not think better than the rest."

Mr. J. Sampson also raised 103 bushels on $2\frac{3}{4}$ acres; and on another field, 2 acres, was raised $37\frac{1}{2}$ bushels to the acre. This last land, it is said, a few years since would not have yielded more than five bushels to the acre, but was improved by two hundred bushels of shell marl and ten horse-cart loads of compost, consisting of the refuse of skin dressers, glue boilers, &c.

The crop of wheat in the District of Columbia partook much of the character of that of the adjoining States, and, as a whole, was a good one.

The wheat crop of Texas, so far as we can learn, was abundant; but we have no means of estimating the amount of the same with any degree of reliance on our conclusions.

In addition to the accounts and estimates already given, it may be well here to subjoin some general views of the wheat crop throughout the country, taken from the public journals since the harvest.

The Albany Argus estimates the wheat crop as follows; which, as will be seen, corresponds pretty nearly with our own independent deductions:

"First, as to the great northern staple, wheat, the crop is undoubtedly a large one—more than an average—and it has been secured in excellent condition. This is the tenor of advices from all quarters. Even in Ohio, where the wheat crop is probably less than an average, the wheat is very clean and the berry very white. We hear neither of rust nor smut. Though the farmers have lost in quantity, they have undoubtedly gained in quality. In Michigan, Illinois, Wisconsin, and Iowa, the wheat crop is magnificent. Every thing has been favorable. So likewise, we understand, is the wheat crop in Pennsylvania. In Virginia, Maryland, North Carolina, and Georgia, it has been affected by the drought—some say so seriously as to shrivel the berry. In Tennessee, Kentucky, and Missouri, the crop is a noble one. In New England and New York, it is probably less than an average one."

Similar, also, is the conclusion formed by the editor of the Journal of Commerce:

"*The Crops.*—Within the last two or three weeks we have travelled 1,000 miles in the State of New York, and every where have made it a point to observe and inquire after the crops. The uniform testimony in regard to *wheat* is, that the crop is beyond an average. We, however, saw many fields which did not come up to our expectations, while others were as good as could be reasonably desired. Passing into Canada, we found the wheat crop there also very fine. Gentlemen from the interior gave the same account. We also saw persons from Michigan, Wisconsin, Ohio, Illinois, and other western States. Even in Ohio, the crop is now thought to be a full average. In Michigan, Wisconsin, and parts of Indiana and Illinois, it never was surpassed. The accounts from Pennsylvania are also favorable. In Virginia the crop is a full average, and in Maryland more than an average. To make a long story a short one, it may be said, in general, that the *wheat* crop of the country is one of the *largest* in quantity, and best in quality, that ever was gathered."

Some of the public journals have estimated the whole wheat crop as high as 125,000,000. We believe this is very much too large, and that it will not overgo 107,000,000. We prefer to fall short than to exceed the actual amount; and, by as careful review as we have been able to make, we have accordingly fixed it, as in the table, at 106,548,000 bushels.

As a general remark, however, it may be said that, in its weight and ap-

pearance and fitness for use, the crop is at least 10 per cent. better. The excellence of the crop, as a whole, seems attributable in a measure to the cold spring and the warm weather immediately succeeding, by which it was protected from the fly and rust, ripened finely, and was gathered in free from damage by unpropitious harvesting. If we might hazard a conjecture, also, we should say that the seed now in the ground being free from insects, the crop of the next year, if the weather proves favorable, will be much improved. It is evident that there is a large surplus of wheat in our country; and the vast quantity which has been poured forward to the Atlantic ports from the western country shows that this surplus has been providentially directed at a period when it cannot merely aid in feeding our own population, but also those who are starving abroad.

While collecting the notices of the crops, we have met with a variety of articles in the agricultural journals and newspapers of the day, relating to the insects and diseases affecting this product. Some of these, and also remedies against them, we subjoin, either in whole or substance, believing that they may be useful as memoranda to the agriculturist; and in some, if not in all instances, when more thoroughly tested, may receive confirmation.

The instances recorded, which have fallen under our eye, of the prevention of smut, (especially the dust or pepper brand, as it is sometimes termed,) by brining and liming, are frequent. One of these we find in a letter to the editors of the National Intelligencer, from C. B. Hamilton, near this city, in which the crop from seed which had not been so prepared was destroyed by smut, while that which had been so prepared remained untouched. The Hon. William Carmichael, also, in a note to the American Farmer, refers to the experiments of M. de Bombasle, who used 18 lbs. of Glauber salts to 22 gallons of water, as a steep; following this with placing his seed-wheat in a bed of quick-lime (slacked just before use) on his barn floor, and stirring it up so as to cause the lime to adhere to the kernels of grain, and then spreading it out to dry, not leaving it more than three days before planting. Mr. Carmichael states that he has tried the same plan, and found it successful. Mr. W. Rayley, of Aurelius, Washington county, Ohio, states to the editor of the Ohio Cultivator, that he has used brining for sixteen years, and thus secured his wheat from the wheat-fly; while his neighbors, without this preparation, have been often troubled by it. A similar testimony as to its efficacy is given in the same paper by A. Wattles, of Chickasaw, Ohio, who says that his limed wheat is one third heavier than the other. The following are some of the remarks of the editor of the Ohio Cultivator on the subject: "*The mode of preparation* is as follows: (it can be varied to suit convenience)—One or two days before sowing, put the seed into a vat or box, then take strong brine (such as is used for preserving meat) and heat it as hot as you can bear the hand in, for five seconds, and pour this over the wheat, stirring it the meantime with a scoop or shovel till the whole is completely wet; two or three quarts of brine is sufficient for a bushel of wheat; let it stand a few hours to drain, then spread it on the barn floor and sprinkle it over with fine slacked lime; stir it and add lime until every kernel appears white and dry: it is then fit for sowing. It will only require about one bushel of lime to ten bushels of wheat.

"Another simple method of brining wheat is, to put the seed into a bushel basket, and stand this on a common wash tub with slats across, then pour on the brine, shake the basket, and allow the surplus brine to run through

into the tub below, to be used over again. The *rationale* of such preparation is this:—First: it is believed that the seeds of disease, as smut, &c., and the minute eggs of insects, as the weevil, exist on or within the kernels of the grain, and are destroyed by the brine and lime. Second: it is known that salt and lime are highly conducive to the health and growth of the wheat plant, especially on soils that have been exhausted of their mineral salts, and where these necessary elements of the wheat crop are not restored by good tillage."

A person writing to the editor of the Albany Cultivator from Laurens district, S. C., says: "I have been soaking my *seed wheat* in bluestone, (sulphate of copper,) one pound to five bushels—water enough to cover; leaving it to soak for about twenty-four hours, and then rolling it in ashes, and have found this method a full preventive against smut. With the same effect I have tried, for five bushels of seed wheat one pound of saltpetre, two pounds of Glauber salts, two pounds of copperas; and I never had smut in wheat when I used either of these preparations."

The editor of the Genesee Farmer gives an account of the appearance of an insect in some wheat which Gen. Harmon, a man thoroughly acquainted with the culture of this product, supposes may be connected with the causes of the malady—Thus: "We saw yesterday, at General Harmon's, twenty or more small brown bugs, which have lately emerged from kernels of smut wheat, leaving a small opening in the grain of smut, like the aperture in the pea, through which the pea bug escapes. General H. placed full heads of smut, before the wheat was ripe, into a closely wrapped paper, for the purpose of seeing if any insect would be developed in the heads of smut. The insect and heads were together when we saw them yesterday. Mr. Harmon thinks that this insect is somehow the cause of this malady. At Mr. Elisha Harmon's we saw a head of wheat free from smut on one side, while every kernel on the other was nothing but smut."—*Genesee Farmer.*

We find an interesting statement respecting the weevil, in a communication from Kentucky to the American Agriculturist, from which we now quote it:

"*A new fact.*—It is generally believed that the eggs of weevil deposited in the grains of wheat are hatched out in the same season before winter; or, if not hatched out *then*, that they perish and do no injury to the grain. This may be the case with the white weevil, but it is not true of the black. In the fall of 1843, two years ago, I received from Virginia a shot bag filled with *Conner* wheat—an early ripening variety, much valued by some farmers in that State. It was a fair, sound, beautiful sample of grain. I had just sown before its reception a small quantity of the same variety, and determined to keep this to sow the next year, fearing some accident to the seeded crop. The shot bag of wheat was very carefully put away in a clothes press—so carefully that it did not again come to light till about ten days ago. On opening the bag a number of black weevils were seen, which had come out. Others were in the act of coming out of the grain; and, on cutting open grains which appeared sound, the insect was found in the grain. Do not the eggs of insects remain dormant, like seeds of plants, till the proper conjuncture of circumstances for their active existence takes place? This may not be for years, or may happen the same year.

"The black weevil also hatched out of grain here *of the present year's*

harvest, for one of my neighbors culled from his field a small sack of wheat he thought might be a valuable kind, cleaned it out, and suspended it by a rope in an upper room of a house. When he took it down to sow, a few weeks ago, he found great numbers of black weevil hatched out, since harvest, in his sack of selected wheat. The conclusion at which I arrived is, that no season favorable to the active life of these insects has occurred here in 1843 or 1844; but that this season, being favorable, not only those deposited this year, but those also remaining dormant in the grain, deposited in previous years, have been excited into active existence. Great injury has been done by these insects this year in this State, and much of the wheat cleaned out has been destroyed by black weevil; and, in cases where it was got out of the straw and left in the chaff, it has been injured by white weevil—a circumstance causing astonishment; as leaving it in the chaff has been thought a sure preventive of injury by them. The wheat left in the stacks till this time is also generally injured, and, in some stacks, utterly destroyed by the white weevil. Can any of your correspondents tell us how to avoid these injuries to the grain after it is made?

"JOHN LEWIS.

"Llangollen, Ky., *October* 18, 1845."

A new insect in wheat is described by a correspondent in the Cultivator for May, from Bucks county, Pa. He says: "It is a small green worm, about an inch in length; its head is brownish green, with two brown spots upon it. The worm ascends the stalk of wheat soon after it has put out in head, cuts off the head, and feeds upon the top of the standing part." He apprehends great injury to the wheat crop there, unless some remedy is discovered, and supposes it may be the army worm; but the editor of the Cultivator speaks of it as new to him.

Another insect is thus noticed in the Prairie Farmer, as found in Illinois: "We are informed that a very singular and destructive insect has made its appearance in parts of Will county, where it makes itself very disagreeably destructive. It is a small fly, a little more than one-eighth of an inch in size when grown. It has four wings, which, when folded upon the back, present the shape of a diamond. They were discovered at wheat harvest, when their presence was indicated by the heads of wheat turning white. The insect was found in myriads, covering the straw, particularly about the joints. Upon touching the wheat stalks they would fall, as if dead, to the ground. When the wheat was cut they took to the cornfields, if near, where they are now making themselves much at home within the husks or under the sheaths about the stalks. Corn which was not too far ripened when they found it, died immediately. They are now preying on the young wheat, which they eat off just beneath the surface of the earth, taking all clean as they go. They are in all stages of growth, and have been from the first; and the ground is perforated with holes made by them. Their scent is that of the bed-bug, and a field of them is anything but delightful. The ant-eater, which preys on the aphides, preys also on this insect."

While upon this subject, we may mention an essay on the wheat fly, by Dr. Asa Fitch, published originally in the New York Quarterly Journal of Agriculture and Science, as a pamphlet which contains much valuable information for farmers in the wheat-growing States. In a letter from Professor Johnston, the eminent agriculturist of England, addressed to Charles

Fox, of Gross Isle, Wayne county, Michigan, (and published in the Michigan Farmer,) by whom he was consulted on the cause and cure of smut and rust in wheat, the Professor says: "About the smut and rust, your notice is all right—steeping in a solution of salt that will float an egg, and then drying the wet seed with quick lime; fermented urine, blue vitriol, (*sulphate of copper*,) and arsenic, are also used as steeps for the same purpose of killing the fungus, with greater or less effect. The rust arises from the over-luxuriance of the growth of your wheat, which will diminish; but especially from the wetness of your soil, or the rains and mists to which, in the midst of so much water, your land may be subject. A good dose of lime, perhaps *plastering* your wheat, might help this disease; but it will lessen as your land is better drained, and rendered drier."

And in relation to rust in wheat, we add the following statement, which may deserve some notice:

"A correspondent of the Genesee Farmer states that he has recently examined many rusted stalks of wheat with a magnifying glass of a very high power, and finds the outer covering of the straw burst open, the edges raised up, and through the apertures thus made the particles of rust protrude. The appearance of the rust he states to be that of dried mucilaginous matter. The rust in this case examined must not be confounded with the red rust, which is entirely external, and can be washed off."

Further accounts of methods of preparing seed-wheat to prevent disease, &c., will be found in connexion with several articles on the culture of wheat, &c., in the appendix No. 2.

The statement in the appendix signed "A farmer in Tompkins county" taken from the Cultivator for January, 1846, is one deserving of attention. Another, in the same paper of July, 1845, contains an extract from Vancouver's Survey of Devonshire, England, in which the surveyor ascribes the rust and mildew to weakness and tenderness, in consequence of late sowing and bad situations. He says: "District No. 1.—The mildew or rust is but little known, except in small enclosures and low situations, where the crop is excluded from a free circulation of air; in the higher parts of the country where the fields are large, and the division mounds are covered only with dwarf hazel or willow and creeping brambles, the evil is by no means such as to require particular notice. District No. 4.—Late sown wheat is found to be particularly subject to rust or mildew, and is much complained of. No. 5.—Wheat sown late is always more or less injured by rust or mildew. No. 6.—When turnips fail, the land is sown with wheat, the early sown crops of which are the best sample, and by far the freer from rust or mildew. No. 7.—The late sown wheat is always very liable to rust or mildew."

Sir John Sinclair, in his Code of Agriculture, (a standard work,) after a full discussion of the subject, recommends, as prevention of rust: 1st, cultivating hardy kinds; 2d, early sowing; 3d, raising early varieties; 4th, thick sowing; 5th, changes of seed; 6th, consolidating the soil; 7th, using saline manures; 8th, improving the course of crops; 9th, extirpating all plants that are receptacles of rust; 10th, protecting wheat plants by other crops. In some parts of the country, however, it is said that early sowing will expose the crop to the ravages of the fly. At a late meeting of the Academy of Science in France, M. A. de Jussieu said that he had recently seen several ears of wheat which had been attacked by the ergot. It is well known that this disease is generally almost entirely confined to rye.

The following method of managing seed-wheat is given in a public journal, as derived from an experienced wheat grower. It may be interesting to some:

"Before entering upon his harvest, he selects a portion of his field for seed, and reserves that for his last cutting. As his harvests are large, this portion gets fully ripe before he is ready to cut it. After drawing and mowing away the rest of his crop, he secures this also; but, instead of placing it in a mow or stack, he puts it on a scaffolding over his barn floor. This is done to prevent the seed-wheat from being affected by the steam which rises from wheat, and which he thinks would injure it. When seeding time comes, he threshes out his seed, and sows it *without any preparation.* He has pursued this course a number of years, and has never had smut in his wheat to any extent since he adopted it."

Besides the varieties of wheat which have been already mentioned in the account of the crops above, we may here notice some others, which seem to possess qualities which entitle them to consideration. A kind called the Etrurian wheat, introduced by Commodore Stewart, possessing, as is said, all the advantages of the Mediterranean, and has, besides, a remarkably strong and vigorous stalk, has been cultivated with success by the Rev. Daniel Zollickoffer, of Maryland. Accounts of this variety may be found with that of others yet to be mentioned, in appendix No. 2. Two other kinds are thus noticed in the American Farmer. Mr. Smeltzer's letter will also be found in the appendix No. 2, just mentioned. Samples of some of these kinds of wheat, as well as the Etrurian, have been received, and will be distributed from the Patent Office to the members of Congress.

"The Baltimore American notices a specimen of white wheat, very remarkable for its extraordinary size, which was grown on the farm of Mr. Joseph Pearson, about three miles northwest of Baltimore, who has this year raised about three hundred bushels, the produce being estimated at forty-five bushels per acre. The stalks are about six feet high, very stout at the bottom, and the grain fully one-half larger than the ordinary red wheat. The strength of the stalks enables it to stand the wind and rain, and it is said to be entirely exempt from smut.

Several years ago, Mr. Pearson purchased and sowed a quantity of wheat procured from New York; among which several heads appeared towering several feet above the other grain. These were carefully collected, producing about a gill of grain; and, in a few years, Mr. Pearson has succeeded in raising from them the quantity above mentioned. He supposes it to be a species of Chinese wheat, the description of which it closely resembles." In a letter received at the Patent Office from Messrs. Pearson, relating to this wheat, it is said: "This present crop was sown after the middle of October, last year. It was soaked over night in brine strong enough to bear an egg, which will float any *cheat*, *garlic*, or other trash that might be in it and assist in sprouting; it is then drawn off, spread upon a floor a short time, and sown."

Again: "Mr. Henry R. Smeltzer, near Middletown, Frederick county, Maryland, has raised this year, from $4\frac{1}{4}$ acres, 212 bushels and 43 lbs. of wheat, which is over 50 bushels to the acre. It is called the 'Oregon.'" The Catoctin Enterprise says the land was carefully surveyed by George Bowlers, esq, and the wheat threshed by the machine of the Rev. Mr. Henry, who saw it measured. It was sown on the 5th October last, not quite $1\frac{1}{2}$ bushels to the acre; it is of a beautiful bright red color, and smooth

chaff. Mr. S. also raised the "China" wheat, which yielded, as near as could be ascertained, about 47 bushels to the acre; this is a most beautiful white wheat, ripens early, and is said never to have been injured by the Hessian fly, mildew, or smut. This and the "Oregon" is on sale by R. Sinclair & Co.

A letter to the editor of the "American Farmer," from R. E. C. Downes, esq., Church Hill, Dorchester county, Maryland, says: "I have just seen a bunch of perfect wheat, of the yellow-bearded variety, consisting of 76 stalks from one grain. The stalks are nearly all of the same height, good heads, and perfectly ripe. It was raised within a few miles of this place, and has been left here for exhibition, and to be forwarded to your city. I have never before heard of any thing like it, and it is quite a curiosity of the wheat crop—at least to me."

"*Washington wheat.*—This is a white-bearded wheat, with very large well filled heads, offered for sale at Coates's seed store, Market street, Philadelphia. It is part of the produce of a single head of 21 grains, which came from Italy with Greenough's statue of Washington, and sent from Washington city by Hon. O. H. Smith, of United States Senate, to his nephew, William Parry, of Burlington county, New Jersey, who has given it its present name."

Another kind of wheat, a small quantity of which has been received and will be distributed, is called the Aguirre wheat, from Spain, which promises to be a valuable acquisition. The account of it from the Albany Cultivator, and in the letter of Mr. Townsend, will be found in the appendix No. 2.

A variety of wheat called the Alabama or Hackleman wheat is mentioned also in the Ohio Cultivator, an account of which will also be found in the same appendix.

The American Farmer for August mentions a sample of wheat grown by Thomas Duckett, some of the heads of which yielded 100 grains. This was raised, he states, on a field from which two consecutive crops of corn had been gathered.

Some objection has been made to the Mediterranean wheat, and the price reduced. The American Farmer notices this fact, and furnishes a method of remedying the difficulty, as follows: "The price of this wheat is about five to seven cents less than other varieties; and the flour made from it, to a considerable extent, has been reduced, by the inspectors, in the standard. In a recent visit to Washington county, Maryland, we mentioned this fact to our friend, Mr. J. Funk, on Beaver creek, a gentleman noted for the excellence of his wheat crops, having raised thirty-three bushels per acre in succession off the same field, with no other manure than that obtained from the barn yard. He informed us that such had been the case in his vicinity, but that when his grain was sent to mill, he directed that notice should be given a day before grinding; accordingly, he repaired to the mill, spread out the wheat, and sprinkled it with water, and thus left it till the following day, when it was sufficiently dry to grind; and his flour was equal at least, if not superior, to that from wheat of any other variety."

A variety of interesting articles relating to the culture of wheat, &c., which have been gathered from periodicals and journals, both of our country and from abroad, will be found in appendix No. 2, among which we would mention, as particularly deserving of notice, the utility of deep ploughing, charcoal as a manure, the views of Mr. McVean relating to the

wheat districts of New York, and the remarks of the editor of the Ohio Cultivator as to the wheat crop for 1846, with experiments in wheat culture, &c., proper time of sowing, &c., McNaill's and Underhill's statements respecting the culture of wheat, &c.

A mode of putting in wheat, called *ribbing*, as practised in England, we find described in the Ohio Cultivator, by Mr. Noble, of Stark county, in that State, and which the editor recommends as "worthy of trial." We give the extract as it stands in one of the public journals:

"*Ribbing in wheat.*—Mr. Thomas Noble, of Stark county, near Massillon, whom we visited a few days since, practises a mode of putting in wheat that is called, in his native country, (England,) 'ribbing;' and, from his experience in this country, he is convinced that it is superior to the common mode of sowing, at least for his kind of soil, which is a fine hazel loam, or what was called 'oak plains' in that region, and is well adapted to this crop. After the land has been thoroughly ploughed and harrowed, till it is in what would commonly be called good order for sowing, Mr. Noble goes over it with small narrow one-horse ploughs, made for the purpose, and which leaves the land in open furrows four or five inches deep, and ten or eleven inches apart; the seed is then sown one bushel to the acre, and the ground harrowed once over, lengthwise of the furrows. This harrowing brings the seed into the furrows and covers it there, and leaves slight ridges between; so that the plants appear as if drilled in rows, and the ridges afford them protection in winter, and keep the ground in a mellower state in summer, besides affording a freer circulation of air, &c. We think the plan eminently worthy of trial, especially on such lands as are subject to 'winter killing.' It is an improvement on the plan of ploughing in wheat, practised by many. With a gang of ploughs, or a machine for making three or four furrows at once, which Mr. Noble intends to construct for this purpose, the amount of labor will be very much reduced."—*Ohio Cultivator.*

Harrowing wheat in the spring is also stated to be useful, and a correspondent of one of the papers says: "That having, one year, left his harrow in the wheat field all winter, he was obliged to drag it across his wheat when he removed it early in the spring, and that the track of the harrow was plainly perceptible through the season, in the greater thriftiness of that part of the grain. The next year he harrowed a few acres of his wheat as early in the spring as the ground would permit, and found the most beneficial effects. The harrowed wheat grew with remarkable rapidity, and turned out decidedly a heavier crop than any other part of the field, though all was sowed at the same time." The editor of the Michigan Farmer says: "For the extensive growing of wheat, no manure is equal to the large German clover, plastered and ploughed under; and every farmer who will give to his wheat fields every third year a crop of clover, will not 'sacrifice his ultimate interest.'" Another writer recommends the following top-dressing for wheat: "Salt; salt and lime; salt, lime, and ashes; soot; soot and ashes, make excellent top-dressings for wheat. If salt should be applied alone, two bushels to the acre is the proper quantity; if salt and lime, two bushels of salt and ten of lime should be sown to the acre; if soot alone, from ten to twenty bushels per acre; and if soot and ashes, ten bushels of each will form a most valuable mixture."

It is often desirable to calculate the amount of the wheat crop as it stands on the ground; and this is said to be done in England with very considera-

ble accuracy, in the manner thus described: "About the time the wheat is blooming, generally about the beginning of June, (winter wheat in England,) a person will go round with a gauge secreted in a hollow cane, which forms, when opened, a triangle, and represents a certain portion of an acre of ground. This is placed over various portions of the crop, in the best and in the worst parts of the field. The number of ears of wheat within the triangle is counted, and the probable quality of the grain is taken into calculation, according as the spring has been wet or dry. On the former supposition, the grain is likely to shrink; on the latter, to harden and come out plump. It may be observed, that if there has been a good general rain during the last ten days of April, and the first ten days of May, on the average no more wet is required in that climate (England) for wheat. An expert gauger will form a very accurate estimate of the probable produce of a given district by this method." The editor of the Maine Farmer states that, by actual counting, it has been ascertained that a bushel of wheat, weighing 62 pounds, contained in round numbers about 550,000 kernels; so that if we were *sure* that every grain sown would grow and come to maturity, taking 42,360 square feet for an acre, and dividing each foot into four compartments, and placing a grain of wheat in the centre of each, the whole acre would only require four-fifths of a bushel.

We add here a statement, which we find in one of the public journals, respecting the difference of weight in a bushel of wheat in some of the States, as it sometimes may be useful. The writer says:

"As I have seen some statements in the papers as to the weight of a bushel of wheat raised by some farmer in Pennsylvania, I would remark that the Pennsylvania bushel, and that generally used in Maryland, is larger than the Virginia standard bushel by nearly three half pints. The greatest weight I have seen, to which the Pennsylvania wheat reached, was 69½ pounds to the bushel. My friend and neighbor, Mr. William Pendleton, had a bushel of seed wheat, of his raising, by the Virginia standard measure, weighed accurately on the flour scales (patent balances) in the Honeywood mills, which weighed 68½ pounds strong draught."

"*Grain measures.*—By a law of Indiana, passed last winter, the weight of a bushel of grain is fixed as follows:

A bushel of merchantable wheat shall be taken and given, in all contracts, at sixty pounds.

A bushel of rye shall consist of fifty-six pounds.

A bushel of corn shall be taken at fifty six pounds.

A bushel of flax seed at fifty-six pounds.

A standard bushel of merchantable barley shall consist of forty eight pounds.

A standard bushel of oats shall consist of thirty-three pounds.

These weights of the respective grains now constitute in Indiana the legal standard bushel; and, under a contract to deliver so many bushels of grain, the delivery of these weights per bushel will constitute a legal tender."

Professor Lindley, of London, speaking of the maturity of grain, says: "It is a remarkable fact, that the further north *grain* can be made to grow, the shorter is the period of time in which it comes to maturity. It has also been observed, that when it is grown in the extreme north, when used as seed in the southern country, it gives its first produce more speedily, ripen-

ing in a much shorter time; although at the second sowing it loses its quality."

In the New York Farmer and Mechanic, the quality of wheat raised in different sections of the country, and the kind of manure which may be used to advantage in the production of this grain, are thus stated: "Wheat is known to be the most nutritious of all grains, because it contains a larger quantity of gluten. But I do not know that it is generally understood, except by scientific agriculturists, that this quantity of gluten may be varied both by climate and the character of manure; yet such is, nevertheless, a well-attested fact. 1st. Wheat of warm climates has more gluten, is harder, and less easy to grind. The difference between the two, in climates not very distant, may be safely calculated thus:

	Warm climate.	Cold climate.
Starch - - - - -	56.05	71.49
Gluten - - - - -	14.55	10.96
Sugar - - - - -	8.48	4.72
Gum - - - - -	4.90	2.32
Bran - - - - -	2.30	
Water - - - - -	12.30	10.00
	98.58	99.49

2d. The gluten of wheat may be increased by the character of the manure used, thus:

	Gluten.
Wheat, average crop - - - - -	19.00
Wheat raised on soil manured with ox blood - -	34.24
Wheat manured with human urine - - -	35.01
Wheat manured with human fæces - - -	33.94
Wheat manured with horse manure - - -	13 68
Wheat manured with cow manure - - -	11.96

From so much of the above facts as show how far climate varies the quantity of gluten, it results that there is a great advantage in Alabama wheat over the northern. Now what is this advantage, as applied to practical purposes? I will explain. Two pounds of Cincinnati flour was weighed out, and to it was added one quarter of a pound of yeast; two pounds of McAlroy's (Alabama) flour was weighed, and in like manner was added one quarter of a pound of yeast; both were accurately weighed in the same scales, and at the same time, and both made into loaves and baked in the same oven. The result was as follows: The Cincinnati flour yielded a loaf weighing 3 lbs.; gain $\frac{3}{4}$, or 33 per cent. McAlroy's flour yielded a loaf weighing $3\frac{1}{2}$ lbs.; gain 4.14, or 55 per cent. *The gain in Alabama flour* 22 per cent.! or, every five barrels of Alabama flour is equal to six of northern flour. But, says one, the northern flour must be the better; because, look at the loaf; it is whiter and lighter. True; but let it be remembered that this difference with respect to whiteness, is the difference in the preparation and grinding; and that of lightness, is chiefly in the absence of gluten. The quantity of the flour may be affected by the mode of preparation and grinding; but the quantity of the several principles composing it

cannot. The same quantity of starch, gluten, &c., must be retained, whether the wheat be ground in a good or bad mill."—*Mon.*

These facts are interesting, and deserve attention. We have already given some account of the Alabama or Hackleman wheat, as it is termed in anOhio paper.—(See appendix No. 2.)

BARLEY.

The crop of barley in the State of New York, where more than half the crop of the whole country is grown, was in general a very good one—better than in the previous year. Taking the census of that State for the year 1844 as our basis, we have found it necessary to increase the estimate in the table. The accounts we have received respecting it, except in some few sections, are most limited. In the northeastern section of the State it was about "10 per cent. more." On the eastern side of the Hudson, below Albany, it is considered as having been larger than in the previous year, and in some counties "15 or 20 per cent." West of the Hudson, and below the Mohawk, while it fell off in Schoharie county, it was a fair average in Otsego county. On the Mohawk, also, and above, it was also "an average crop." Still further to the west and to the north, it varied from "10 to 15 per cent. increase." In the more western central counties, and in the western part of the State, the increase in some sections was yet larger; "20, 25, 30," and even in some cases it is thought to have been as high as "50 per cent." As the barley crop in this State is shown, by the late State census, to have been previously under-estimated, the amount of the crop will be comparatively larger than it would otherwise have been. We suppose it may have reached an average of about 15 per cent. more than in 1844, according to the State census.

In some of the New England States the crop is said to be "coming more into repute every year. Its excellent qualities for feeding give it great commendation; and its value as a crop to stock after is surpassed only by the wheat crop." Of the crop in Maine and New Hampshire we can gather but little, except that upon the whole it was a better crop—probably 5 per cent. more. In Vermont it was equal or something better than the crop of the previous year, and the increase may be fixed at the average crop of about 5 per cent. In Massachusetts, in the eastern sections of the State, though but little was raised, there was probably an increase of 10 to 15 per cent. The same was likewise the case in the central part of the State. In the western, however, it is thought to have fallen off, from the drought which prevailed in June and July. On the whole, there was an average crop of 8 per cent. The crop in both Rhode Island and Connecticut is small, and may have been about the same as in the adjoining States. So little attention, comparatively, is paid to this crop in nearly all the remaining States, that it is difficult to arrive at any very satisfactory estimate. It was, as is supposed, about an average crop in New Jersey, and considerable less in Pennsylvania, as it suffered severely by the drought. In the southeastern, eastern, and central sections, it is thought to have fallen off from "25 to 30 per cent.;" and, taking the whole State through, we believe it must have been less than the crop of 1844 by "about 10 per cent." In the States south of Pennsylvania, for the most part the decrease must have been equally large, if not larger, from the same cause. They, however, produce so little, that the general result can be but partially affected by this

diminution. In an agricultural paper in Virginia, however, it is thus recommended:

"*Barley a profitable crop.*—There is constant demand for this article in the west, where the consumption of malt liquors is immense. It is a very sure crop, and liable to none of the diseases peculiar to wheat; yields about double the quantity, and commands a higher price. Those who have cultivated it in this vicinity, we understand, have succeeded well. We make the following extract from an article on the subject in the last number of the Winchester Virginia Farmer: 'The cultivation of barley has been of late years much neglected in Virginia. We find, however, here and there some few of our friends disposed to give it some degree of attention, as a grain worthy their notice; and, among those who have been the most successful in producing a fine crop, we would note the case of our friend, Mr. John Bruce, of this place. From a four-acre lot we are told this gentleman raised, during the present season, two hundred and ten bushels of clean barley, averaging, as will be seen, fifty-two and a half bushels per acre, making the round sum of one hundred and fifty seven dollars and ten cents, and, after deducting interest of land, cost of labor, seed, &c., yielding him the handsome profit of one hundred and twenty dollars. Now, if there is any other crop that comes up to this, or any farmer who has derived a greater profit in cultivating the same number of acres in small grain this season, we should like to hear from him. When we take into consideration the fruitful yield of barley, and its freeness from fly or other infections so common to wheat, we are strongly of opinion that it bids fair to become a great staple in portions of the valley. The Winchester brewery will give seventy-five cents per bushel. It is required to weigh forty six pounds to the bushel.'"

In Tennessee and Kentucky—which, however, raise only a small crop—there was about an average yield; perhaps "a slight advance" on the crop of the previous year. In Ohio, on the eastern central border, there was a considerable falling off; probably "30 per cent. less." In the more northern counties it was "about equal" to the crop of 1844. In the northwestern part of the State a slight increase; perhaps "10 per cent. more." In the southwestern, from the central, "25 per cent. more." In the Miami valley, however, the individual crops probably fell as much as "25 per cent." On account of the increased demand, there is said to have been much more cultivated; and thus the whole crop in that section is thought to have reached as high as "75 per cent. more" than in the previous year. More than half of the whole crop of Ohio, as it appears from the census, is raised in some half dozen counties of the State. Taking the whole State, we are inclined to believe that there was an increased crop of 10 to 15 per cent. more than in the year before. In Indiana, Illinois, and the other western States, we believe also there was a small increase; and in Michigan, Iowa, and Wisconsin, which rank higher in their attention to this crop, a very considerable advance. The crop of Iowa is estimated, by one whose opportunities of judgment must be allowed to be good, at 30,000 bushels. We suspect, however, that this is rather too large an estimate, though our own of the preceding year was much too small evidently, as the crop of Platt county alone is said to be 5,000 bushels. We think that Wisconsin was probably about 20 per cent. more, and Michigan in the same proportion. The whole barley crop, therefore, would amount to about 5,160,000 bushels.

Some mention was made in the report for 1844 of a kind of barley called the Emur barley. We notice a few observations respecting it during the past year, in the Cultivator for October and November. The first is from a correspondent who is spoken of as W. B., of Laurens district, S. C., who was very anxious to obtain some of this kind of barley. "He formerly had it, but lost the seed by suspending the business of farming for a few years, and removing to another district. He says: 'I am fully satisfied, from the trials I have made, that it will produce from 30 to 50 bushels per acre, and that our soil and climate will suit it. It will bear stable manure; whereas, the increased application of that article to wheat invariably tends to throw it into straw, and causes it to lodge.' He offered five dollars for one bushel of it, delivered at any seaport and shipped to Charleston." The editor of the Cultivator remarks: "We cannot see, from this description, how this barley differs from the naked or bald barley, which has been more or less known in the country for several years." In the November number of the same publication, the editor observes that a sample of the bald or naked barley has been sent him by John D. Spinner, of Herkimer. He states that it is a handsome grain, and weighs above sixty pounds to the bushel, and is said to be very productive. Mr. Henry Brewer, of Enfield, New York, also mentions in a letter alluded to in the same work, that he sowed half a bushel of "skinless" barley in the spring on seventy-two rods of ground, and the produce was sixteen bushels, weighing fifty-eight pounds per bushel. It was much injured by the drought and grasshoppers. He thinks it, however, a valuable kind of grain, and says that it makes good flour, which is preferred to buckwheat for cakes. In the Mark Lane Express for July 21, 1845, this grain is thus characterized:

"This valuable grain is worthy the serious consideration of the agriculturist, as returning a greater profit than the barley in general cultivation; and, if grown side by side, will yield more bushels, more flour for human food, and 25 per cent. more beer, and also will feed more stock; because—

"1. It contains more flour than any other grain, rice only excepted.

"2. It weighs more than sixty pounds per bushel.

"3. The flour is whiter and sweeter than common barley flour.

"4. The flour absorbs more water than other flour; consequently, it produces more weight of bread.

"5. Bread made from any barley flour is better made into thick cakes; and if from a fourth to an eighth of an ounce of carbonate of soda is dissolved in the yeast, it improves all bread, and takes the bitter taste away.

"6. By plain boiling, it is good food for children.

"7. The malt made from it increases in measure more than from common barley.

"8. The malt will make in seven days less than common barley.

"9. It can be made one month earlier and one month later than from common barley.

"10. It weighs considerably more than the malt from common barley.

"11. The quantity of beer made from this malt is 25 per cent. more than from common malt, and of superior flavor.

"12. Three bushels will seed the land as well as four of other barley.

"13. It should be sown in March or April.

"14. It ripens in eighty or ninety days only.

"15. If sown without grass, it can be harvested in two or three days.

"16. If sown early, it may be harvested in time for a following good crop of turnips.

"17. It only requires the same cultivation as other barley.

"18. The straw is much superior for fodder.

"19. It very seldom lodges, and is not subject to disease.

"20. Each acre of this barley produces about one-third more food.

"N. B.—The produce of this barley, both in quantity and weight, surpasses all others; and, as regards its malting qualities, and extract of saccharine, is even *superior* to the best Chevalier barley in quality as well as quantity." —*Northampton Herald.*

In the Mark Lane Express for September 8, 1845, a new species of barley is mentioned, which, upon a light soil, produced from 8 to 10 quarters (equal to 64 to 80 bushels) per acre. It is said to be fine in quality, and good for malting purposes.

Efforts have been made to procure some Himlaya barley, mentioned in a previous report, but as yet they have been unsuccessful. There appears to be some diversity of opinion on the continent respecting the value of this grain, as we learn from some of the German journals received at the Patent Office.

OATS.

Oats being a favorite crop, and raised more or less in every State, seem to have been extensively cultivated; but the drought affected the crop more than usual in some parts of the country. In New England, on the whole, it appears to have succeeded. The Maine Farmer, in July, says that "oats are rather light, but will undoubtedly yield a remunerating harvest." In the central and northern section, also, we are informed that there was an advance of "10 per cent." over the crop of 1844. In the lower section of New Hampshire, on the southeast, it is thought that the increase was at least "10 per cent.;" in the central lower section there appears to have been a decrease; and in the central western, a good judge, after reviewing the weather, both before and during the harvest, states the crop to have been "an unusually large one, as more than common was sown." On the whole, regard being had to this product as set down in the census, we may fairly estimate the increase at from 10 to 15 per cent. for the State. In Vermont the crop was a good one; and, from all that we can learn respecting it, there was an average increase of about 10 per cent. In Massachusetts, in nearly every section of the State, there was a gain, ranging from 10 to 15 per cent. In the eastern central part, the crop was unusually early, and did well. In the western section it is thought to have fallen off perhaps "one-third," which is ascribed to the drought in June and July. A writer from that section, in a letter to the Boston Cultivator, says: "Oats seem to be going rather out of fashion, as well they may; for every year proves them to be an exhausting crop, and a miserable one to stock with." In the western part of the State, according to the census, the oat crop is usually larger than any other; and, after comparing the accounts in the various counties with the returns of the census, we believe that the crop must have had about the average increase of a good crop; "about 10 per cent." over that of 1844. In Rhode Island and Connecticut, also, more was sown and raised, and the gain was probably about the same as in Massachusetts. The crop fell off in New York. The accounts from all sections nearly unite in the testi-

timony to this effect. The State census, which we have taken as our basis, shows that our estimate the last year was too great. The drought very seriously affected the progress of the crops in all parts of the State; but in some sections the injury was greater than in others. In the southeastern section, and along on the Hudson river, either side, where large quantities are raised, it probably fell off from "20 to 25 per cent.;" and, in some cases, the decrease has been estimated as high as "50 per cent." As we proceed north, however, the damage sustained does not seem to have been as great; and, indeed, in the northeastern and northern portions of the State it is thought to have been better by from "5 to 10 per cent." Along the Mohawk, it was "about an average crop;" but south of this again it fell off considerably. As we proceed west, in the central portion it is variously estimated to have been "10, 15, and 20 per cent.;" and still further west, (with the exception of the southwestern corner, where, on account of more having been sown, there was a slight advance,) the crop declined, as is thought, about one-fourth. The decrease, therefore, in the whole State, can hardly be estimated at less than about 10 per cent. on the crop of the State census of 1844. The oat crop of New Jersey was, also, less than that of the preceding year. In the central counties, across the State, it is estimated at "one-third less" than an average crop. In the northwestern section the decrease is thought to have been not quite so great, but perhaps "about 10 per cent." On the whole, it may have fallen off about 15 or 20 per cent. from the crop of 1844, which season, it will be borne in mind, was favorable to this product.

The prospect of the crop in Pennsylvania, in the spring, seems to have been promising. Thus, in May, the Germantown Telegraph says: "Spring, thus far, for oats, which are already several inches high, could not have been finer. A considerable extent of ground is occupied this year with this grain, which, judging from present appearance, will turn out well."

In the months of June and July, however, the drought very seriously impaired this prospect, so flattering; and it is stated in the public journals that "oats promise to be only tolerable." Since the harvest, also, we have similar reports from various sections of the State. In the rich agricultural county of Lancaster it is thought that this crop was "40 per cent. less;" and it is said: "Oats, in consequence of the dry weather in April and May, were short in the straw and light in the grain; the deficiency is not short of 40 per cent., as compared with the preceding year, and of an inferior quality at that." In Chester county the crop suffered much from the drought in June and the early part of July, and is probably "50 per cent. less." In the eastern central section, near the Delaware and Lehigh rivers, the same complaint is heard of drought, and the crop is thought to have decreased from "15 to 20 per cent." In the northern central counties, lying on the Susquehannah and its branches, it is judged to have been about the same as last year. Lower down, however, on the same river, and west, there was a falling off of not less than "one-fourth of the crop." In the northeastern and northwestern parts of the State, also, there was a falling off of from "5 to 15 per cent." The crop for the whole State, it is believed, suffered a decrease of 15 to 20 per cent. The same may probably be said of Delaware.

The early accounts of the oat crop of Maryland are discouraging. Thus the Centreville Gazette speaks, respecting that of the Eastern shore: "The

oats are fast ripening, and will soon be ready for the cradle, though there was but a light sowing, and the prospect is not very flattering."

Subsequently, the American Farmer says: "The oat crop will be short, though not so light as had been anticipated a month ago. Some late rains helped the oats which had not been too far advanced to be affected by it, (the drought.) On the Eastern shore of this State, it is said the crop will not probably exceed half the usual one." By some persons the crop of the northeastern section of the State is thought to be "50 per cent. less." There can hardly have been a less deficiency, throughout the whole State, than about 25 per cent.

The Southern Planter, speaking of the oat crop in Virginia, in June, says: "Notwithstanding the oats have put out prettily since the late rains, they were so retarded by the drought that the crop, we should think, must of necessity be a short one." Again, In July, an account from Richmond states: "There has been a sad falling off in oats, many farmers deeming their crops scarcely worth gathering, they being 35 cents per bushel." Since the harvest, also, a correspondent of the Southern Planter writes from Lynchburg; and, speaking of the crop in the valley, says that there "is not one-quarter of a crop of oats." Other accounts likewise concur in representing the oat crop of Virginia as having been a light one. In the counties lying east of the Blue Ridge, and stretching up from Bedford to Madison, the report is that this crop was "almost totally destroyed by the drought." In the section directly east of this last, it was also "almost an entire failure—from 50 to 75 per cent short." In the southern central part of the State, bordering on North Carolina, it is also thought to have been "50 per cent. less." In the northwestern corner of the State, and also in the counties lying along the Kanawha river, the decrease is estimated to have been not less than "25 per cent." Such being the views which every where meet us respecting the oat crop of Virginia, we believe we shall not very greatly err by fixing the decrease as high as 40 per cent.

In North Carolina the drought likewise seriously affected this crop, and in all sections it fell off—some say "50, others 75 or 80 per cent." We judge it to have been about 50 per cent., or not more than half the usual crop. The same was the case in most parts of South Carolina and Georgia, though in the latter State, in the northwest corner, there is supposed to have been a much better crop; and the whole deficiency, therefore, may not have been more than about 30 per cent. compared with the crop of 1844. The like diversity respecting the oat crop is found in our accounts from Alabama. In the southeastern part of the State, we are informed by a good judge that the crop was about equal to that of the previous year. In the northeastern section it is estimated at about 15 per cent. more. In the central portion, on the branches of the Alabama, the drought is much complained of, and it is supposed that there is not more than two-thirds of a crop. On the whole, it is judged that the deficiency may have been about 15 to 20 per cent.

In Mississippi and Arkansas, there appears to have been a small increase; perhaps 10 per cent. above the crop of 1844.

In Tennessee the oat crop is said, on the whole, to have been better than in 1844. In the northeastern section, from the central, it is thought to have been less than that of the previous year by "about 20 per cent.;" while at the western part of the State there was, it is said, an equal advance. It may be fixed at about 10 per cent. for the whole State. A similar diversity exists in Kentucky; though, taking the whole State through,

the crop is an increased one. In the northeastern section of the State it was probably an "average crop." More towards the centre, the oat crop was probably "less by 10 per cent." In the southeast, "10 per cent. better." West of the centre, in the northern part of the State, it was "20 per cent. better;" while in the south, bordering on Tennessee, it is estimated to have been "less by 20 per cent." than the year previous. The whole crop was probably about 10 per cent better.

With few exceptions, the accounts relating to the oat crop in Ohio are favorable. In the eastern central section, bordering on Pennsylvania and the Ohio river, there is said to have been "not more than half a crop." In the southeastern part of the State, on the Ohio river, also, there was "not more than two-thirds of a crop." In the central counties, lying on the Muskingum and Scioto rivers, they are stated to have been "good," "a full crop," "25 per cent. more," &c.; "large, but not of the best quality." Still further south, "about 10 per cent. more." East of this last, "about 25 per cent. more." In the southwestern corner "the oats were much injured in the early part of the season from the drought, yet the frequent rains during the whole month of June caused a decided improvement to take place, and tolerably good harvests were anticipated." Later, the crop is considered to have been "an average one," while further east and north it is pronounced to have been "first rate;" "25 per cent. better." In the northwestern corner of the State, bordering on Michigan and Indiana, it is thought to have been "20 per cent. more;" further east of this, along the lake, it was "about 25 per cent. better;" while north and northeast of the central section it was also "25 per cent. more, as a much larger quantity was sown." We have estimated the whole crop of Ohio at an increase of 20 per cent. over the crop of 1844.

In Indiana, Illinois, Missouri, and Michigan, which raise large quantities of oats, the crop, in its early prospects, was also promising; and it was probably at least 20 per cent. more than in the previous year. In some sections of these States, the increase is estimated as high as "33 or 50 per cent."

The prospect of the oat crop in Wisconsin is thus stated, under date of Racine, July 15: "Oats bid fair to be an excellent crop, the slight rains and warm weather having enabled them to recover from the blighting effects of cold and dry weather of May and the beginning of June."

The crop of Iowa was also better than in the preceding year. For both Iowa and Wisconsin, we have estimated the advance at about 20 per cent. The crop is a favorite one, and the number of emigrants into these Territories is large; and, if any thing, our estimate may probably be too low. The whole oat crop for 1845, therefore, we fix at 163,208,000 bushels.

The following crop of oats we find stated in one of the papers, and it must be allowed to have been a heavy yield:

"*Large yield of oats.*—It is stated in the Racine Advocate, that Edward S. Blake, of Racine county, raised on one acre and one-sixth of land, this season, one hundred bushels of oats."

In the New York Farmer, of October 16, 1845, we find an account of a species of wild oats, which appear to be considered as valuable for fodder. We give it as we find it in the above named journal:

"*Wild oats.*—I have received from Captain Post, of Deep river, (Conn.,) a package of the grain of wild oats, and also a bundle of the heads of that grain. Captain Post states that he has about 10 acres of this aquatic grain;

and that from his youth up he has noticed that it was visited by the wild duck, blackbirds, and rice-birds, but did not know the cause until his attention was called to it by a paragraph of mine in relation to wild rice, which he saw a few weeks ago in your paper. He remarks that his neighbors were as much in the dark as himself. Since he read the paragraph referred to, he has made a full examination, and finds that the straw of this aquatic grain will yield about four tons per acre, and is as useful for cattle fodder as are corn-blades. A short time ago I received from Captain Post some of the blossoms of these oats, and several plants, with the roots attached, which I have heretofore noticed. The straw is near 10 times the size of that of wild rice, a specimen of which I have lately had from Rice lake, while the grain is only about half the size. I am of opinion that this grain will become a valuable aid to the farmer, and therefore it is that I call public attention to it. I shall exhibit some of this grain at the office of the Farmer and Mechanic. Yours, &c.,

E. MERRIAM.

In the Mark Lane Express, for September 15, page 15, we have the following account of remarkable oats:

"At a late meeting of the East Derbyshire Farmer's Club, Mr. Holbrook, the secretary, exhibited some specimens of oats, the stems of which were six feet six inches in height, and the diameter five-eighths of an inch. One plant produced 130 corns of oats, and another more than 300. The oats were dibbled in, the rows being fifteen inches apart, and the plants six inches asunder. The ground which produced these extraordinary specimens had been parched and burned."

The London Gardener's Chronicle contains the following:

"*On the choice of a variety of oat for cultivation.*—Strongly suspecting that the real value of different varieties of oat was unknown, and that weight by bushel was even less applicable to this grain than to wheat, I procured samples of nine sorts, carefully selected by Messrs. Lawson, of Edinburgh. I have not had them compared chemically; I leave that to those great and wealthy bodies associated for the ostensible purpose of conferring benefits on the farmer. I have followed a simple mechanical process, which any one may follow. The weight of each sort per bushel having been ascertained, the following table was constructed according to the results:

	Weight per bushel of
Siberian oat	45 pounds
Sandy	$52\frac{1}{4}$
Kildrummie	42
Early Angus	42
Hopetoun	41
Potato	$41\frac{1}{2}$
Early Dyock	$40\frac{1}{2}$
Late Angus	$40\frac{1}{3}$
Black Tartarian	39

The useful part of the oat being the kernel, and it being probable that the proportion of the weight of the husk to that of the kernel might vary so much as to render the weight per bushel a deception, 100 parts by weight of each sort were taken, and the husk and kernel carefully separated. The following table shows the result:

In 100 *parts by weight*—

	Husk.	Kernel.
Sandy oat - - - -	21	79
Early Angus - - - -	21	79
Late ditto - - - -	21½	78½
Potato - - - - -	22	78
Early Dyock - - - -	25	75
Black Tartarian - - - -	25	75
Hopetoun - - - -	26	74
Kildrummie - - - -	28	72
Siberian - - - -	31	69

It is curious that the oat at the head of the first table should be at the bottom of the second. There may be as great difference among oats as among wheats in regard to their nutritive qualities; and until this shall have been ascertained by the chemist, we shall not know the real comparative values. In the mean time, there need be no hesitation in preferring the sandy oat over all others, as it is very early and very productive in grain and straw."

RYE.

Nearly the whole rye crop is raised in a half-dozen States. Of these, the State of Pennsylvania ranks foremost, and New York next; then New Jersey, Kentucky, &c. In Pennsylvania, according to the census of 1840, a dozen counties in the eastern district raised one-half of the whole crop in the State. The accounts received respecting the rye harvest in these heavy counties, is, in general, favorable. In Lancaster and vicinity the rye is said to have "suffered somewhat from the late frosts in the spring, as it had done the preceding year." The amount, however, is supposed to have been as large as (perhaps somewhat larger than) in the previous year, and of a better quality. Similar are the reports from Chester, Bucks, and Lehigh counties, and vicinities. In Adams and York there is thought to have been a large increase—even as high as "50 per cent." The winter was favorable, as well as the dry weather in March and April, and later during the filling season, so that there was no mildew. In the central section, east and northeast, there was also an increased crop of rye. In the northwestern part of the State, also, this crop is described as having been very good; "equal to ten per cent." advance. On the whole, therefore, we think the rye crop in this State was probably fifteen per cent. better than in 1844. In New York, also, nearly five-sixths of the whole crop is raised in the part of the State which lies east of the centre, and of this more than one half is not a great distance from either side of the Hudson and Lake Champlain. In all these sections the report is favorable, varying, upon an average increase, "10, 15, 20, 30, and even as high as 40 per cent." In the other parts of the State, there seems to have been more sown, and in only one case do we observe any mention of failure or diminution. Taking the State census returns of this crop, which reduces our estimate of 1844, we have added about 20 per cent., supposing this to be a fair rate, in view of all the information we have been able to gather respecting the rye crop for the whole State.

In New England, so far as we have been able to ascertain, there has been a slight increase. As wheat has become more profitable and less subject to

destruction from insects, and rye is less used for distilling than formerly, it has very considerably fallen off for a few years past. In Maine, New Hampshire, and Vermont, the crop has probably increased about 5 per cent.; while in Massachusetts, in the sections where more than half the crop was raised, according to the census of 1840, it has fallen off, as estimated, from "5 to 25 per cent." In the western part of the State, the rye crop is said to have been "injured by a late frost in May, about the time it began to head, and the consequence was that it did not fill well; the heads grew full length, and a good share of them did not have half the number of kernels they should have had, and probably the heads most forward received the injury. We are inclined to think, therefore, that, taking the whole State through, there was some falling off—perhaps 5 to 10 per cent. A similar estimate appears to be demanded as to the remaining States of New England.

Of the rye crop in New Jersey—which State raises a comparatively large amount of this product—it is stated that in the central counties it was "a fair crop," and in the western ones it was "15 per cent. better." These two sections of the State, as appears by the census of 1840, raised more than one-half of the whole rye crop; and in view of the crops in the adjoining States, combined with such other information as we could obtain, we have fixed the advance of this crop in New Jersey at about 15 per cent.

But a small crop is raised in Delaware, yet there was probably a slight increase.

In Maryland and Virginia, also, there seems to have been an advance. In the northwestern part of the latter State there is thought to have been "25 per cent. more;" but this is too high for the whole. We suppose that if we take into view the influence of the season, &c., already adverted to in the wheat crop, it could not exceed 10 per cent. in either of these States. In the southern States, generally, there is comparatively little rye, and it is quite difficult to obtain any satisfactory information respecting this crop.

In North Carolina the crop fell off from "10 to 15 per cent." on account of the drought in the sections where at least one-half the whole crop returned by the census of 1840 was raised. In many of the other portions of the State, also, the drought, as we learn, was severe in its operation on the crop. It is therefore believed that there has been a diminution of this crop of about 15 per cent.

In South Carolina, in the counties which, according to the census, gave about one-half of the crop, the decrease of the rye crop is variously estimated from "10 to 30 per cent." We have placed it for the whole State at from 15 to 20 per cent. less. It will be remembered that the early drought in this State was most severe in its effects.

The same seems to have been the case in Georgia.

In Alabama, Mississippi, and Arkansas, we believe there may have been slight advance.

In Tennessee and Kentucky, an increased crop. In the latter State it is variously estimated at "an average;" "10 per cent.;" "20 per cent. more." These sections, thus given, according to the census returns, include the part of the State where more than one-half of the whole crop for the State is raised. In the other sections, so far as we can judge from the information respecting the influences operating on the progress of the crop, there was a similar diversity of opinion. On the whole, the increase may be estimated at about 10 per cent.

Considerable diversity of opinion also exists respecting the rye crop of Ohio. In the central, eastern, and north of central sections, there seems to have been a falling off, varying from "25 to 50 per cent." This quarter of the State, according to the census, raises about one-quarter of the whole crop. In the southwestern and northwestern sections, which include about another quarter, there seems to have been a gain of "25 per cent. and upwards." An extensive distiller in one of the southwestern counties estimated the increase in that vicinity as high as 100 per cent. The causes of failure assigned are, that a less quantity of rye was sown, and the drought affected its growth. On examining the census in relation to the remaining contiguous sections to those above mentioned, we find the more northern and central counties gave the heavier crops; and in these, from such information as can be procured, we suppose the crop to have been somewhat deficient. We apprehend, therefore, that the crop in the whole State must have been less than in 1844 by about 5 per cent.

Similar to the above is the diversity of opinion in regard to the rye crop in Indiana. Some allowance must be made for the greater quantity of land cultivated, as well as the increasing population. Still, however, it is a small crop; and while in some sections the advance was "25 per cent.," in others it fell off "20 per cent. or more." On the whole, the increase was probably not over 5 per cent.

The same was the case, it is believed, in Illinois and Missouri; though the increase in some sections of the former State is estimated as high as 10 per cent.

In Michigan, the gain on the previous crop is by some persons estimated at "25 per cent." We are inclined to think, however, that for the whole State it did not exceed 10 per cent.

In Iowa and Wisconsin there was some advance in this crop.

The whole rye crop for the United States may, therefore, be estimated at 27,175,000 bushels.

A fine sample of rye is mentioned in an agricultural paper, (probably the American Farmer,) and is described in the extract following: "*Rye, tall and short.*—Mr. Editor: All our farmers ought to know that the kind soil of Maryland is still capable of being easily improved, so as to yield abundantly the necessaries of human life and pleasure. The large sample of rye now sent to you was sown about the 1st of September last, (say a half bushel to the acre,) to test its capacity for branching in rich ground, which appears to be very great, as there are thousands of similar bunches in the field whence that bunch was taken; and each bunch is the product of a single seed, yielding thousands. The next smaller sample was sown thick, about the 10th of October last, and was mowed off close to the ground on the 23d of last April, when it was all out in head, and three to four feet high, yielding a large crop of good hay. It then sprouted from the roots again; and that is the second growth, which has so far matured in about 60 days. It should have been sowed on the 1st of September, and the hay crop taken off by the middle of April; then the second would be perfect by the 1st of July. The smallest sample was derived from a handful of rye sown as thick as the grains could lie side by side, in the same field; and at the same time the second sample was sown. The result was, that they were too thick to thrive; hence they yielded nothing worth saving. The products of our soil are improved as much in quality as in quantity, by good ground and good cultivation. Agriculture is the most important busi-

ness in the world; and yet no business appears to be less understood or more neglected.—*Thomas*.' The above, from an old and experienced farmer near Ellicott's Mills, was accompanied by the three specimens of rye alluded to; and while the first is truly '*tall rye*,' (nearly 7 feet,) and well filled, the smallest ($2\frac{1}{2}$ feet) looks more like *chess*, or cheat, than any thing we have seen, for many years, not to be that pest of the wheat field. The second specimen is about 5 feet."

The value of rye as a means of fodder for sheep, is stated in a letter contained in the Ohio Cultivator, as follows: "*Sowing rye for wintering sheep.* The following suggestion, though not new, may prove of value to many persons at the present time; and we thank the writer for calling it to mind. —*Editor.*

"HAYESVILLE, *Richland co.*, *Ohio*, *June* 27, 1845.

"MR. BATEHAM: From the present prospects in this part of the State, hay will be very scarce and dear next winter, and something, as a substitute, seems to be wanting among our farmers. The following plan for wintering sheep was suggested to me by an old practical farmer, and I think will commend itself to the reason of every one. He says he has tried it, and he has found that his sheep do better than by any other way. When ploughing his corn for the last time, when it begins to tassel out, he sows the ground with about a half bushel of rye to the acre, which grows up about knee high by the time winter begins. Sheep will feed upon this rye all winter, and want no other care, except a good shed to run under in stormy weather. In the spring, if farmers prefer a crop of corn or oats upon the ground, they can have it. If they think the crop of rye will be profitable, all they have to do will be to let it grow. Yours, truly,

"J. H. COX."

In the Landwirthschaftliche Dorfzeitung, or Village Gazette, of July 26, 1845, published at Leipsic, we find mention of a species of rye called the gigantic Siberian rye, a translated description of which we subjoin: "The gigantic stalked rye, known also by the name of the Siberian rye, must be the most excellent of all the kinds of rye hitherto cultivated, on account of its wonderful and gigantic product of grain and stalk, as well as the weight and goodness of its kernels. Six metzen, Prussian measure, (about 18 quarts English,) of this rye, are enough for sowing a morgen, (a little over five-eighths of an acre,) from which, on a well-fitted and prepared soil, in favorable weather, we may count on a harvest of 24 bushels. The single stalks of this rye reach from six to seven feet in height, and bear thirty to forty ears, which are from five to six inches long. [The Austrian and Prussian inch and foot are both somewhat longer than the English.] The grains themselves are much larger than the usual rye; a scheffel of it (a little over a bushel and a half English) weighs from 90 to 92 pounds; (a pound is larger than the English pound;) and in a drachm is contained only about 80 kernels—a proof of its goodness and weight. This rye, also, on account of its thin hull, gives an excellent flour. It must be sown at the end of August, or the beginning of September, that it may have time to acquire sufficient strength before winter. Pasturing it in the autumn with sheep has hitherto had no injurious effect, either on the crop of grain or straw."

The account is in a letter signed Von Plotho, of Magdeburg. We have been unable to find any description of, or allusion to, this description of rye

in Lawson's Agricultural Manual, Loudon's Encyclopedia, or Johnson's Cyclopedia; from which we infer that it is probably unknown in England or this country, and may deserve further inquiry, and perhaps importation and trial.

The Siberian oats are by some, in England, preferred to the Poland oats.

BUCKWHEAT.

The buckwheat crop of the New England States seems to have been better than in some years. It is, however, but little noticed in the agricultural papers; and hence it is not easy to form any very accurate estimate of its amount of production. We notice in particular only a few States, respecting which we have been able to ascertain with more precision. In New Hampshire—in the western part of the State—we are told that, "having had the benefit of rains, it has yielded a very good crop." In the southeastern section, though but little is grown, it is thought to have been "5 per cent. more," and "an average crop" in other parts of the State. The same was the case in Vermont. In Massachusetts—in the northeastern section of the State—it is judged to have fallen off "10 per cent." There is, however, very little cultivated. There was more in the central part of the State; and in the western it is variously estimated from "20 to 25 per cent. better." Of the latter section, it is stated: "The buckwheat crop is peculiar to itself; its growth is quick, and it commences blossoming early in its growth; and upon the same stalk you may see the blossom and the grain fully ripe. A fall crop and cool weather are necessary in maturing. The present season was favorable." The crop for the whole State was probably about 10 or 15 per cent. more than in 1844.

New York stands among the foremost of the States wherein this product is cultivated, and the crop appears to have been "somewhat better" in the northern; "not so good by 20 to 30 per cent." in the river counties generally; "about as good as usual" along the Mohawk; "poorer" to the southward of this section; and further west, in the central portions, and tow[ards] Pennsylvania, to have fallen off "15 to 25 and 30 per cent." In the southwestern corner of the State it is said to have been "a trifle better." As the decrease took place in some of the counties which furnish the heaviest crops of buckwheat according to the late State census, the crop must have fallen off very considerably. The buckwheat crop there was estimated too small in the previous year.

In the State of New Jersey, which raises a comparatively large crop of buckwheat, (in the western part of the State,) this crop is said to have been "30 per cent. better" than in 1844.

The Belvidere Apollo thus speaks of buckwheat in Warren county: "Our neighborhood was visited by a white frost yesterday morning. Fortunately, a considerable part of the unusually large buckwheat crop of our county is cut, and much that remains standing is so far advanced as to be out of danger of injury from the elements. Our mention of a large crop means, that an unusually large quantity of the grain was sown, and that the yield will be generally heavy. We shall give our lowland friends substantial proof, presently, that 'auld Scotia' is not the only 'land o' cakes' in the world." In the central section, comprising Burlington and Monmouth counties, it is, however, supposed that this crop fell off largely, and the de-

crease has even been estimated as high as "one-half." Still, it is believed that there was a gain in the whole State of 15 or 20 per cent.

Pennsylvania furnishes about one fourth of the whole buckwheat crop, and its appearance the past season seems to have been quite different in the various sections. In Lancaster, and in some of the southeastern counties, there was "some advance"—from "10 to 25 per cent." In the former county it is stated that "the absence of frost to a period later than usual in autumn, must have had a favorable influence; which, taken in connexion with the fact that more of this grain was sown in consequence of the failure of wheat in places, warrants the conclusion that the crop may be fairly set down at 25 per cent. more than that of last year." In the eastern central section, lying along the Delaware and Schuylkill, it might have been "about 10 per cent. better." In the northeastern part of the State the increase did not probably exceed "5 per cent." It looked well in the early part of the season; but owing to the drought and early frost, there is not so good a crop. In the counties lying on the Susquehannah—both those bordering on Maryland, and those which occupy the central upper portion of the State—there was a decrease, it is thought, of from "25 to 30 per cent." In the northeastern part of the State there was a gain of "10 to 15 per cent." In comparing the information respecting different parts of the State with the census statistics of this crop in the same sections, we find that there was an evident gain, taking the whole State through, of 10 or 15 per cent.

Maryland raises but little buckwheat, and therefore we have but little information respecting this crop in that State. In the northeastern section it is estimated that there was a decided increase, and probably this was the case in the whole State.

In the northwestern part of Virginia there also appears to have been some gain on the crop of 1844.

In North Carolina it fell off. We have not, however, given our estimates in the table for this crop in these States.

In Tennessee and Kentucky there was also a small advance.

The accounts from the various sections of Ohio respecting the buckwheat crop are all favorable. In the north central portions, on the Reserve, as much more was sown, the crop is thought to have been more than double that of the previous year. The range of district lying west and northwest from this latter, also, it is believed, had a better crop by "25 per cent." In the northwest corner of the State, also, the increase is fixed at "one-half more." In the southeast section from the central, the crop of buckwheat was also considered better by "one-quarter to one-third." In the eastern central part, bordering on the Ohio river and Pennsylvania, it is judged to have increased "about 10 per cent.;" while in the southwest part of the State, from the centre, it was fully an average crop. In view of the census statistics for these different sections, in relation to the buckwheat crop, we believe that we shall not greatly err by estimating the increase to have been about 20 per cent. above that of the crop of 1844.

There is not a great deal of buckwheat raised either in Illinois, Indiana, or Missouri; but there was probably an increased crop also in those States. In Illinois the advance in some sections is fixed as high as "one-half."

Michigan exhibited a better crop of buckwheat the past season than in the previous year. The editor of the Michigan Farmer rates the advance for the State as high as "50 per cent." This is high authority, but we prefer to put it somewhat lower—say "30 per cent.;" as in some sections it has

fallen off as it is stated. In other sections it ranges from 10 to 50 per cent. advance.

The crop was a fair one in Iowa and Wisconsin. Taking the whole, the aggregate crop of buckwheat for the United States will be about 10,268,000 bushels.

MAIZE, OR INDIAN CORN.

This, as it is well known, is the largest of all the grain crops. Its importance is also fully appreciated, as there is no product which is common to all the States, that is so extensively cultivated. The varieties in the different sections are numerous, and continually increasing by improvement and the introduction of seed from abroad. As it is so generally cultivated, there is more frequent mention of its appearance and progress in the agricultural papers, and the public journals generally. A better judgment can thus be formed respecting it. The prospects of the corn crop in the summer in almost all parts of the country, especially along the Atlantic States, were most unpromising, especially from the drought. The evil, however, did not prove to be so great as was feared in some sections, though in others the corn crop suffered most severely.

New England, in proportion to her population, raises a large corn crop. In Maine the crop was about an average one. The Maine Farmer of July 11 speaking of its appearance, says: "A part of the corn crop looks very well bearing a good color, but rather dwarfish in size. Much of it, on this route at least, is afflicted with the *yellow fever*, or some other *yellow* disease; or else, as the boy said, the seed planted must have been the *yellow kind*. At all events, it has the yellow hue upon it, which is not a very flattering omen of a fair harvest. We have had too many cold days, and still colder nights, for the successful growth of corn. Our most congenial seasons for this crop do not yield a great harvest; yet many farmers every year succeed in raising enough for their own use."

In New Hampshire, as early as August, we are told, in an agricultural paper, that this crop "looks promising." In the southeastern part of the State it is said that it was probably "10 per cent. more." One informant adds, that "it is undoubtedly increasing in quantity; and next to wheat, it is considered the most desirable crop. The fodder from a good crop of corn is worth nearly as much as a crop of potatoes, and it is a fact that wheat will grow better after corn than after any other crop." Further to the west it is thought to have been "10 per cent. less." Higher up, on the Connecticut river, we are told, by a competent judge, that "Indian corn stood the drought remarkably well, and has given a very fair yield; except here and there, perhaps, upon knolls, and ridges, and high plains of a light dry soil." Estimating the crop according to the relative proportions given by the census statistics of this crop, we are inclined to believe that there was some increase—perhaps from 5 to 10 per cent.

The accounts from Vermont in all sections represent the crop to have been a fine one. The drought does not seem to have prevailed so greatly there as in some of the other New England States. The Burlington Press speaks of it as "uncommonly large and fine." The section of the State lying in the northeast corner, and along the Connecticut river south, also, we are informed, enjoyed a long warm season; and hence the crop is thought to have been "20 per cent. better." In Windham county it was a

fine crop; and it is stated: "Muck is the secret cause that has given us a greater growth of Indian corn than has ever been known in this county. Seven acres, presented to our own fair by seven different individuals residing in different towns in the county, gave an aggregate growth of 740 bushels, or about 106 bushels to the acre." The whole crop of the State, therefore, was probably as much as 20 per cent. more than in 1842. The drought severely affected the corn crop in the eastern part of Massachusetts; in the middle it was not so much felt, and still less at the western. In most of the towns in the northeast and central Atlantic counties it fell off from "10 to 25 per cent." In the interior, it is thought to have been "about 10 to 15 per cent. better." The Greenfield Gazette, in July, speaks thus of it: "Indian corn looks middling well, but needs more warm weather and rain; the corn will be generally good." In the western part of the State, we learn from the Boston Cultivator that the prospect was poor. A correspondent says: "*Indian corn.*—Any one acquainted with the season may well wonder that there is any growing. It has had many and severe obstacles to contend with; for, in addition to the cold, unpromising May, it was thoroughly cut down by the frost on the 8th or 30th of that month. It, however, started again; and though backward, it now gives, if the season hereafter is favorable, a tolerable prospect of a good crop." At a later date, however, since the harvest, an informant writes to us: "The Indian corn has not been better with us for many years. The season, after the 1st of June, was warm, dry, and uniform, which is natural to this crop. Some pieces on dry land were affected by the drought; but, as a general remark, the season was admirably adapted to this crop. The report of the committee in Berkshire county on about 20 pieces was over 100 bushels to the acre. It is thought to have been in that section "25 per cent. more" than in 1844. We presume the average increase for the whole State was about 10 per cent. The crop of 1844, it will be recollected, was a good one.

The corn crop of Rhode Island is described in July as being very promising, and there seems to have been at least 15 or 20 per cent. more. Great fears were likewise entertained in Connecticut on account of the drought, and many pieces of corn suffered. Had not timely rains at last been enjoyed, the whole State would have experienced a great falling off in the crop. The injury, however, did not prove so serious as had been apprehended; and on the average, probably, we may allow an increased crop of about 10 per cent. over that of the preceding year.

The prospect of the corn crop during the summer in New York was most discouraging. The apprehensions entertained were not, indeed, realized to their full extent, though there has been some decrease. A New York agricultural report, for the months of July and August, speaks thus of this important product:

"For July, *corn* has had a miserable chance, and the only wonder is that it looks so well. It is now in tassel; and if we had had even a moderate supply of rains, the yield would have been very great. The ground is now so parched that the leaves begin to curl; and, unless we have speedy showers, the crop will suffer greatly."

In August: "This great staple never ran so narrow a chance of a total failure as this year. At the close of July, farmers had serious thoughts of cutting up their corn for fodder; the leaves were curled up; the silk appeared, but without any signs of the ear filling out. Fortunately, the rains

came on just in time; the color is now changed, the ear is full, and the crop is saved; an early frost would not even jeopard the prospects of the farmer."

In the western part of the State, a Buffalo paper gives the following statements of the corn crop in that vicinity for June and July:

"The corn crop, of which the most dubious forebodings have been indulged *by some* in this quarter, has as yet exhibited no feature to warrant the conclusions that have been arrived at. Farmers know that corn does not require hot weather before the 1st of July; and that to be killed down by frost when two or three inches high, is far from certain damage to the crop. Prior to July, cool, damp weather is favorable to corn. This forms the roots; while July and August, if hot, complete the crop, and insure a rich harvest."

Again: "*Indian corn.*—This important crop may yet be a fair average. Much, however, depends upon this month, and the first two or three weeks in September. If we have warm weather and frequent showers, and the frost holds off till past the middle of September, we shall have a good crop."

In August, we have the following notice from the Batavia Times: "*Corn* is now going ahead rapidly, and there is every indication that it will turn out well."

In September, mention is made in one of the public journals of a whirlwind, which passed through the northern part of the county of Orleans, leaving "a track of some 160 rods wide, and 17 or 20 miles in length." The *corn* is stated to have suffered in some places very severely from its ravages, especially where it was stacked. The drought was severely felt in the eastern part of the State; and from the information received respecting the crop since it was gathered, we learn that there has been a decrease varying from "10 to 15 or 20 per cent." In the upper part of the State, on the northeast, the crop varied from "5 to 10 per cent. less." Lower down, about the centre of the river counties, the falling off of this product was from "20 to 25 per cent." The same was the case yet further towards New York, for the most part. In some counties, however, on account of the greater quantity sown, the crop was "as good, if not better," than in 1844. On Long Island, at the further part, the corn crop, it is judged, was "10 per cent. less in quantity" than in 1844, but of "a very superior quality." "The drought diminished the quantity to some extent, although a dry season is much better than a wet one for this important crop. The *eight-rowed white Dutton corn* is generally considered the best by our farmers." Many of the ears raised this season, on one farm, are said to have been "15 inches long." In the southeast corner of the State, and back from the river, west, the decrease is said to have been large in consequence of drought; and by some the loss thus sustained is estimated as high as "50 per cent." As a general thing, however, we believe that it was not more than 20 or 25 per cent. less than the crop of 1844. From the southern border of the State, and northward west of Hudson river, and reaching onward to the Mohawk river, there was a gradual improvement. There was more sown in some parts of this section, and the crop is estimated to have increased along the Mohawk valley, and northerly, "10 or 20 per cent." Somewhat further west it fell off; and in the county of Oneida the decrease is said to have been "one-fourth." In the counties northwest of this last, towards the Lake, it was "considerably better." The crop in Onondaga county was

"an average one;" but the drought seriously affected it in Cayuga and Cortlandt counties. More to the southwest, however, it was better. In Chemung county it is said to have been "very fine;" and, including the adjoining counties of Tompkins and Yates, the average increase is stated at about "10 per cent." In Seneca and Wayne counties, it is supposed to have been still more. Further to the west and north, again, the drought seems to have been felt; while in the southwestern and western sections there was an increase estimated at from "15 to 20 per cent." The crop for the whole State has, on the whole, fallen off from that of 1844 (considering that given in the late census by the State as our basis of comparison) about 10 per cent.

In New Jersey, although the drought prevailed, yet there was an average crop; and in some parts, especially in the central counties of Burlington and Monmouth, it is thought there was an increase of from "10 to 15 per cent."

Pennsylvania raises a large quantity of corn; and, judging from the accounts received respecting it, though affected by the drought, it did not suffer equally in all parts of the State. In Lancaster and the southeastern section generally, the amount gathered seems to have been "fully equal" to that of the previous year. One informant says: "In the northern part of the county the season throughout was dry, and the corn crop was light, which was, to some extent, the case last year; but in the southern part of the county, where the rain was sufficient to nourish the plants, the crop was rather superior to that of the preceding year. The average crop for the county was about the same as last year." So of Chester county it is said: "The corn crop, though much retarded in many instances by the ravages of the cut-worm, affords a tolerable average, the fall being very favorable to the ripening of the plant." In the counties of Lehigh and Bucks, also, it is said to have been "very good; equal in some places, and even superior," to the crop of 1844—perhaps reaching as high in certain cases as "20 per cent." More to the northeast, the drought somewhat lessened the amount raised, and it may have fallen short "5 to 10 per cent." In the section on the Susquehannah, and on the Maryland line, comprising Adams and York counties, it is thought to have suffered a still larger decrease, and by some it is fixed as high as "50 per cent. less." This, however, we believe to be too much. In the northwestern part of the State it was a better crop by "15 per cent." On the whole, regard being had to the comparative products of the various sections as exhibited by the census of 1840, we believe that the crop for the whole State may be fixed at an increase of about 10 per cent. over that of 1844.

The same was probably the case in regard to Delaware; which State, in proportion to its population, raises quite a large corn crop.

In Maryland the following are some of the earlier notices respecting this crop. In June, the Torchlight says: "The prospect for *corn* is not so encouraging, the severe drought having injured it to a great extent." In July, from the Eastern shore, the account from Centreville is—"*Corn* looks well throughout the county, and, unless some very injurious drawback occurs, an unusually fine crop may be anticipated." Again: "The belief is general, says the Frederick Examiner, that the corn crop will be a very short one. So great has been the alarm in regard to it, that we have heard of individuals purchasing their corn in advance of the market, and at a high price. But, thanks to an all-wise Providence for refreshing rains lately;

since which the prospect of the crop is brighter." The Baltimore Sun, in the same month, also states: "Corn, as yet, is very promising." In the American Farmer a correspondent, writing from Carroll county, says: "The corn crop with us is good, considering the season. I shall make fourteen barrels to the acre, and perhaps more—the effects of deep ploughing, liming, and close planting." So in August, likewise: "The corn, generally, has suffered very much from the drought. The early planted, in parts of this and many of the adjoining States, will be irrecoverable to a considerable extent; the later planted may do better, if we have seasonable rains this month. We fear it will be a very light crop throughout all the middle and southern States." And, in another journal: "Anne Arundel county, in this State, was visited by a tremendous tornado on Sunday the 3d instant. Fields of corn were literally destroyed, and stripped of every particle of fodder, and all other products of the soil suffered in like manner." Somewhat later we find it mentioned, that in some parts of the State the corn crops are improving, and that there is reason to believe there will be an average crop." From other sources, also, we hear that the crop fell off; and in the northeastern section, especially, it is thought to have done so at least "one-third." It will be recollected that the crop of 1844 decreased from that of 1843. We believe, therefore, that a decrease of 20 per cent. for the last crop, in comparison with that of 1844, may fairly be allowed. The sections of the State already referred to probably raise full half of the whole crop, if not even more.

The early accounts respecting the corn crop of Virginia were not unfavorable. In July, a Richmond paper states that "it will be good, judging from its healthy color." In Campbell and Bedford counties, however, it is stated in another journal, that "this crop is worse than any during the present century." In August we find great complaints of the drought. The following is from the Richmond Compiler: "The corn crops in all eastern Virginia, except in the rich lowlands on the tide-water, will be a failure. The tassels of the corn were destroyed by the intense heat without rain, and furnished very little pollen; the consequence is, that the ears are, a large portion of them, without grains, while few are filled. Some fields look as if they would make a tolerable yield; but, upon taking off the shuck from the ear, an exhibit of grains few and far between is made, which is distressing to the farmer." Again: "The inhabitants of counties within a circuit of one or two hundred miles are now sending to Richmond for meal. Some of the farms on the lower James river will scarcely yield half a crop of corn, even if they now have the advantage of copious showers." The Richmond Whig says that, while particular counties and neighborhoods will fall short of an adequate supply of corn, the aggregate crop in the State of Virginia, in conjunction with large supplies of the old crop which still remain on hand, especially below tide-water, will not only be ample for home consumption, but yield a large surplus for coast transportation. "West of the Blue Ridge, and east of the falls of the rivers," adds the Whig, "the corn crop is believed to be an average one. In many of the midland counties it will fall short. The wonder is that so much should have been made in defiance of so unprecedented a drought. It speaks well for the improved methods of cultivation. Twenty years ago, such a drought would scarcely have allowed seed corn to be raised." The Clarksburg Republican states that, "in northwestern Virginia the *corn* crop will be a very fine one, unless there should be early frosts in the fall." A correspondent of the Southern Culti-

vator for October says: "The *corn* crop is literally cut off." The editor of the Southern Planter for October, alluding to this crop, says: "Upon the subject of the corn crop we have such conflicting accounts that we hardly care to publish them. There is no doubt that the crop, take it all together, will be a short one; but, unlike the tobacco, the corn does not go to a common market; and being, on account of the expense of transportation, confined to narrow limits, the price will vary in different neighborhoods. The unexampled vegetative powers of the month of August worked wonders on the late corn; and, in many places where the farmer had despaired, a tolerable crop has been made. We extract the following from a letter received from a large planter and most valued friend, in Mecklenburg: 'We have experienced one of the most distressing droughts that I have ever known; the few river mills which could grind refused to grind any thing but corn, and it was with great difficulty that the country could be furnished with corn meal for a distance of forty miles around us. The navigation of the Roanoke ceased, and up to the first instant we were actually threatened with a famine; since that time we have had fine seasons, and our prospect for corn has brightened far beyond our most sanguine calculations.'" Later accounts which we have from other sources correspond with the foregoing. Thus, of the central counties of Bedford to Madison, east of the Blue Ridge, our informant says: "Of Indian corn, after minute inquiries in all parts of the district, I am satisfied that there will not be more than half the usual crop. The severe drought, commencing early in the spring and lasting until the first of August, blasted the crop almost entirely in many sections." In the southern central section, bordering on North Carolina, the decrease is estimated at "50 per cent." In the counties lying east of the Blue Ridge, comprising the range on the James river from Campbell to Fluvanna, it is also thought to have fallen off "one-half" from the crop of 1844. In Amelia county and vicinity, it fell off from "25 to 33⅓ per cent." In the northwestern corner of the State, and also in the section lying along Kanawha river and its branches, it is believed to have decreased "25 per cent." Taking the whole State, it is thought that the average deficiency will equal 30 per cent. The following, relating to this crop in different sections, are taken, respectively, from correspondents in the Southern Planter for the month of October, and in the Dollar Farmer. The suggestions in both are valuable.

"About the 1st of August I returned from quite an extensive tour on horseback through the counties at the foot of the Blue Ridge, from Campbell to Orange. I found that the *corn* was almost given up. It was really distressing to see the fields of hard-working poor men, upon which they depended for bread, bearing a slender, sickly looking little stalk, with no ear. Corn had already risen to $3 50 and $4 per barrel, but those who had old corn were holding on for higher prices. I saw many farmers who were eating their wheat, and refused to sell at any price, quite confident that they would not make bread from their corn crops. As I approached the lower country it continued to improve, at least as far as the neighborhood of Charlottesville, where I saw some of the finest corn I have ever seen growing. The corn in the neighborhood is pretty good, though greatly injured by the late unprecedented drought; but this that I speak of was decidedly the heaviest growth of any thing I have ever seen on land. It was the crop of our friend, Mr. W. Gilmer. He resides about six miles west of Charlottesville, and invited me to ride through his field with him to show me his

corn. I will not attempt to describe what I saw: first, my account would be incredible; and, secondly, I could neither do justice to Mr. G. nor to his field. As I said, we rode through it, but it was more laborious than riding in a thicket of woods; for though we went in the widest row we could find, it was difficult to keep the blades and stalk from dismounting me. He has of it, I guess, some fifty acres of immensely rich land, (creek low grounds,) and his calculations are, to make on some 20 to 25, on some 25 to 30, and on some from 30 to 40 barrels per acre. Now this seems wild, but it does not seem so to those who have seen the corn growing. The rows are 5 feet apart, and the corn was literally sowed along in them. I allow that they average 4 inches. Every stalk has an ear or shoot on it, and the tassel was beyond the reach of my cane, and I on horseback; and the stalk has a beautiful color from the root. Mr. G. seemed to think he would make 35 barrels on a considerable portion of his field. I cannot risk an opinion; but if every stalk brings a nubbin, and 1,000 of them are allowed to the barrel, (500 ears is considered the number,) I calculate, from a table in the Farmer's Register, vol. 2, p. 592, showing the number of stalks per acre at given distances, that there will be near 30 barrels."

"I observed that on some of the best lands on James river the corn is tolerably good; that is to say, will yield about one-third as much as the crop on the Kanawha. I perceive that they plant their corn on James river $5\frac{1}{2}$ to 6 feet apart, and cultivate it with ploughs. This is a sad error. It should be planted 3 feet each way, harrowed as soon as up; then a single furrow run on each side of the row, throwing the earth from the corn; then another furrow on each side, throwing the earth back again; and then the cultivator passed *once* through each row whenever grass begins to appear, or whenever the earth begins to bake or become compact. They say their soil is of such a nature that this culture will not do; that it is stiff, and must be worked with the coulter and plough. My answer is, that they have not complied with the requisite conditions. They must plough deep, double-furrow plough, or use the sub-soil plough after a deep furrow of the common plough; and they must make the soil more friable by means of clover, manure, and lime. I know of no soil in Kentucky that requires the coulter in cultivation, or that may not be tended with the cultivator alone, except when the rains are long continued. No soil can be in good condition that will not admit the cultivator. I fix upon 3 feet for the rows, because that is the distance which a good cultivator will sweep clean. It is of the utmost importance that a single passage through each interval should suffice; this enables the farmer always to keep the grass under command, and the soil loose. The great secret in cultivating the soil, as in war, is prompt and rapid movement at the proper time; and promptness, decision, and energy, and an eye that takes in the whole field of operation, are hardly less essential to the farmer than to the general. Hence the extreme scarcity of good farmers. Another advantage in planting at three feet is, that the corn will more readily keep out the grass. From 1 to 4 stalks may be left in each hill, according to the soil and the views of the farmer. I much prefer, after much experience and observation, close planting, and I should leave at least 2 stalks in each hill in the James river lands."

The corn crop of North Carolina also suffered most severely from the drought, as well as the early frost. Thus, in one of the public journals in June, we find it stated that "in Bladen county, N. C., the frost of the 1st of

this month was severe enough to kill corn which was nearly three feet high. One planter had ploughed up a 30-acre field of corn of that description, with the design of replanting it. It is swamp land, in a low situation." In some sections it is said to have been literally cut off; in some sections, however, it proved better than its early promise. Thus, the Raleigh Register says: "The streams all over the country are drying up, and in some parts persons go forty to fifty miles to have their corn ground into meal. In this city many of the wells have given out; a circumstance rarely if ever before occurring. And yet we are astonished to see how well vegetation looks, particularly the corn crop."

"A letter from Halifax, N. C., expresses the opinion that as much corn will be made this year as last, in that region."

Again: "A letter from Hamptonville, Surry county, N. C., speaks of the corn crop, which was then being gathered, as short of an average; it was selling at 40 cents a bushel from the heap in the field. Heavy biting frosts were felt about that time, and the week before they had floods of rain, which was greatly needed, particularly in the counties lower down, to enable their mills to grind. The past summer, in that district, was pronounced 'the dryest of the dry, by the oldest inhabitant.'"

"The crops in this section of the State, as we have before stated, are very fine. In Hyde county, it is thought more corn will be gathered this year than in any one year heretofore. It is estimated that Hyde will export of corn alone 150,000 barrels, or 750,000 bushels; which, at 40 cents a bushel, amounts to the handsome sum of $300,000. Pretty well for one small county of only 6,500 inhabitants."—*Washington (N. C.) Whig*.

Hyde county, lying north of Pamlico sound, and with more marshy soil, it is probable, did not feel the drought as severely as in others more dry in soil, and hence less able to resist the heat, extreme as it was.

The accounts received from the interior portion of the State very generally represent the crops as having suffered greatly, and as having been largely cut off. The range of counties from Ashe to Caswell, in the north and west parts of the State, it is said, did not yield more than "one-third of a crop." So of the western central section, near the Catawba and Yadkin rivers; it fell off "from one-half to two-thirds" from that of 1844. It appears, therefore, from the best information that we can obtain, that there was a very considerable decrease of the corn throughout the whole State; and we feel authorized to fix the estimate, as we have done, at about one third less than the crop of 1844.

As we have already seen, in our remarks under "The Season," the drought was greatly felt in South Carolina; and from the various notices we find respecting it, we believe the corn crop in this State to have felt its effects most severely. The following accounts will enable us to observe the progress of the corn crop in some sections of this State:

From the Charleston Mercury: "*Darlington C. H., South Carolina, June* 30.—We are in the midst of a remarkably dry season—the dryest that has occurred since 1819; and serious apprehensions are entertained for the corn crop, which has now reached the critical stage of shooting, and will soon, without rain, be beyond remedy."

Extract of a letter to the editor of the Charleston Mercury, dated "*Marion C. H, July* 1, 1845.—We have been almost parched up for want of rain, and the crops, with few exceptions, look badly; the thermometer ranging daily, during the last week, at from 90° to 100°. The corn crops, especial-

ly, will be very short, both here and on the west side of the Peedee. Some of the best farmers do not expect to make over half a crop."

Again: "In this section the prospects of the agriculturist are bad—very bad indeed; the corn crop cannot now, under the most favorable circumstances, be much more than half an average one. Those who have a sufficiency of corn, and in ordinary seasons would be willing to part with a portion of it, now refuse to sell at any price. The article has already reached 75 cents by the quantity, and will doubtless soon be $1 per bushel. We have never known a more unfavorable season, or heard more general or well founded complaints, and really fear that there will be much distress before another crop can be planted and gathered. Some fields of early corn we have examined, we feel confident, will not yield as much as the seed planted; and unless we have rain shortly, the late planted corn will be entirely lost."—*Cheraw (S. C.) Gazette.*

"*Abbeville (S. C.) C. H., July* 9.—*The drought.*—The oldest farmers amongst us say that the present drought is unprecedented in the history of this country; and that the wants and distress of many in our district will be great. It is the opinion of many with whom we have conversed, on sale-day, that they may be able to raise corn enough for bread for their families, but not for their cattle. A gentleman, on whose judgment we rely, told us that from 100 acres of corn belonging to one of his neighbors he would not be able to gather much more than a bushel, so completely had the drought destroyed it. On sale day nothing could be heard of but drought and prospects of famine; and the inquiry from every one is, Where can we get corn?"

"The prospects of the planter are not only gloomy, but perfectly desperate. Bottom lands planted in corn will scarcely make one-third of a crop; and most of the high lands in the middle country will yield but little more than the seed which was planted. In addition to all the horrors of destitution by drought, the chinch bug has attacked many plantations with such violence, that, in large fields, not a blade of corn has been left alive. Many farmers are replanting entire fields."—*Columbia South Carolinian, July* 16.

"Let the season be as it may from this out, we believe it is not within the bounds of probability that the corn crop of this State will reach half an average one. So far as our own observation has extended, we have no doubt it will fall short of this estimate."—*Cheraw Gazette, July* 22.

The Georgetown Observer, of July 30, says: "The corn crop is short of an average one."

Later, in August, we find the following statement, quoted from the Richmond Whig, in one of the public journals: "A letter written at Spartansburg, S. C., on the 9th instant, states that a meeting of the farmers of that district was held a few days previous, to take into consideration the state of the provision crop. From the authentic information received by the meeting, it appears that the corn crop of that part of the State will fall off fully two-thirds; and the whole upper country is said to be in about the same condition. The surplus of the old crop in the adjoining counties of North Carolina had been nearly exhausted by the demand from South Carolina, and supplies were being obtained from Tennessee at ruinous prices." The letter adds: "The crop that is now making is almost exclusively confined to the bottom lands; the upland, in many places, is so total a failure that many are cutting down their fields to save the stalks for fodder. There are hun-

dreds of acres that will not make the seed planted. I know men, who in ordinary times are called good livers, that will not make as many pecks as they usually make barrels of corn. Men speak with fear and trembling of the prospect before them; and those who have corn, feel and know that they will not be long better off than those who have none."—*Richmond Whig.*

The Charleston Patriot of August 1st states: "In Richland, Lexington, Orangeburg, Barnwell, and other middle districts in the State, the corn crops in many places are irremediably ruined—literally burnt up along the face of the earth."

The views given above are confirmed by the accounts we have since received from other sources. Thus, in the northeast section of the State, it is thought the injury sustained from the drought was at least "15 per cent." West of this last, along on the Santee river and its two great branches, both the drought and the army worm are complained of, and the crop is estimated to have fallen off "38 per cent." In the northwestern corner of the State, the same complaint is made; the deficiency is believed to have been "one-half," while in Spartansburg, and the counties east, it is stated to have been probably not less than "75 per cent. less" than the crop of 1844, it being "an almost entire failure, except on bottom lands; thousands of acres of land not producing the bushel to the acre of the upland." In the west central part of the State, also, comprising the counties lying between the Congaree and Savannah rivers, the falling off is estimated at "about one-third." It is evident, therefore, that the decrease in this State has been great. In forming our general estimate for the State, however, some regard must be had to the fact that the crop of corn for 1844 was a deficient one. The average decrease for the whole State can scarcely have been less than 35 to 40 per cent.; perhaps even more. The lower counties being more moist, probably suffered less than the upper ones.

We give the following notices, which we have gathered from the public journals, indicative of the progress of the corn crop in Georgia, in July:

"*Sumter county, Georgia, July* 4.—Our section of the county has been injured severely by the drought. The corn crop, in the aggregate, is cut off one-half."

The Hamburg (Ga.) Journal, of the 5th instant, says: "The weather at this place still continues favorable, but warm. The corn crops promise an abundant yield to the husbandman.

"The corn crop continues abundantly promising in many parts of this State, although the back counties are suffering from a protracted drought."

[From the Savannah Republican, July 11.

"*Rain! rain!!*—Yesterday our city and vicinity were blessed with the heaviest fall of rain which has been known since the 1st of January last. The effect on the temperature was very perceptible. We are inclined to think that it extended for a considerable distance along the coast, as well as in the interior. Its effect upon the crops—the corn, particularly—will be slight. In no event can there be more than one-half a crop in the State."

A writer in the Macon Messenger says: "There has been much alarm recently at the prospect of a very short crop; and, consequently, corn has risen to a very extravagant price. It had sold here from $1 to $1 25 a bushel. The price of corn in Savannah is 55 cents a bushel; and some

has already been received from there and laid down here at 65 cents. There is abundance of corn in New Orleans at 32 cents per bushel, and will be furnished here in a short time at 50 cents; on the upper line of Georgia it is selling at 62½ cents." He remarks that, "with regard to the present crop, the prospects are now far better than they have been, and that all the late corn is doing well from the recent rains, and that there is no danger but that plenty will be made in the State to supply the wants of the people, though the early part of the crop has been considered as injured in some small sections; yet, through two-thirds or three-fourths of the State, it is an average one, and in many sections it was never better. Of this he is satisfied, from personal observation for nearly 200 miles, and from authentic information from numerous individuals, both travellers and planters."

In August, in the northwest corner of the State, the Lafayette Herald says: "While accounts reach us, from every quarter, of the protracted drought, we are still blessed with abundant showers, and crops of corn are very promising. If the weather continues seasonable, ours will be the Egypt of Georgia."

In other sections, however, the report is unfavorable. Thus the Griffin (Ga.) Jeffersonian, of the 14th instant, has the following:

"There is no mistake now about the drought and short crops. From all quarters of lower and middle Georgia the report is the same, that the drought is excessive, and not more than half crops of corn can be made."

"The corn crop, also, in proportion to the demand for consumption, is the shortest that has been made within the last twenty years."—*Macon Messenger.*

Again, in a public journal: "One of the most intelligent and observing planters in Georgia has lately made a circuit of some three hundred miles, a portion of it through the very heart of the State, and gives it as his opinion that the corn crop will fall short one-half of what it was last year, if not more. This, we believe, will be the result throughout Georgia; and the greatest *economy* and *liberality* must be exercised to prevent much suffering, or evils of *greater* magnitude." "The corn crop of Georgia is represented to us by some of the Georgia papers as deplorably bad. The water courses were all low, and the mills would have to stop at once, without the blessing of rain."

Our accounts since the harvest refer principally to the northwestern and central sections, west of the Ocmulgee river. In the former, it is stated: "Indian corn is our principal crop, and this has been cut short at least one-third, from unusual drought during the summer." In the latter, it is also thought to have been "not half an average crop." From the accounts thus given, we think we do not greatly err in fixing the decrease at about the same as in South Carolina.

It is probable that in Florida it was very similar. In July it is stated: "*Corn*, however, has suffered greatly from the drought; and, the season being so far advanced, a full crop is not looked for or expected."—*Tallahassee Floridian.*

The following statements are taken from the American Farmer of October last. They confirm the views we have given respecting the corn crops of South Carolina and Georgia. The papers in South Carolina present us with very distressing accounts of the sufferings of the poor, from the failure of the corn crop. The Greenville Mountaineer says that hundreds are leaving the State, and the editor says he regrets the necessity of

advising others to follow them. The Ashville (North Carolina) Messenger says "that numbers of wagons pass through that place daily on their way from South Carolina to Tennessee to procure corn, as the corn crop in a large portion of South Carolina is entirely destroyed. These wagons are sent from 150 to 200 miles for corn! Great numbers of poor people are leaving the State and going to Tennessee. A hundred and fifty persons, consisting entirely of poor families, passed through this place last week." The Georgia Constitutionalist says "that the want of water to turn the mills is another great evil, and, in some instances, they have had to send 50 miles to get meal." The editor of the South Carolina Temperance Advocate says "he has traversed different sections of Lexington, Newberry, Laurens, Greenville, Pickens, Anderson, Spartanburg, and Union districts; and the result is, our firm conviction, founded on close personal observation—fortified, too, by the opinions of judicious men—that the crop of corn will prove well nigh a total failure."

The drought does not seem to have injured the corn crop as much in Alabama as in others of the adjoining States, though it was doubtless somewhat lessened. In May the appearance of the crop was promising. The Gazette of the 14th instant, published at Cahawba, says: "The prospect now is very flattering for good crops. Some of our farmers tell us that they have never seen *corn* thrive better. A great many of the planters in this section have planted more corn than usual, and, of course, a less quantity of cotton." Again, in June, it is stated in a public journal: "The drought, which has threatened some sections of this State, has been happily terminated; the late showers have dissipated all fears as to the result. The gardens have been severely injured, but the *corn* crop will be abundant." So, in July, the Montgomery Journal states that "the corn crop is looking well." In August, however, from Montgomery it is stated that the corn crop will be very short in that section, in consequence of the long drought. In the southeastern section of the State, from a very intelligent informant and a good judge on such subjects, the corn crop is estimated to have been "about equal" to that of the preceding year. In the central part of the State, bordering on the Alabama river on either side, it is said to have been "one-third less," as it was materially injured by the drought. In the northeastern the falling off is represented not to have been so great; perhaps "about 15 per cent." On the whole, for the State, we suppose it may have been about 25 per cent. less than the crop of 1844.

In Mississippi, from what we learn respecting its progress, and the state of the crop when gathered, it also fell off; though not so largely as in Alabama. Thus it is stated in July: Extract from a letter, dated Yalobusha county, Miss., July 13, 1845: "From every appearance at present, the corn crop in this section will fall far short of a good one. There has been but very little rain this season, and that little has fallen only partially, so that a large portion of the country still remains very dry and the corn very much shrivelled."—*Mississippian, July* 23.

Again: The Creole (Canton, Miss.) says: "Showers have been frequent. The crops look as well as could be expected, but neither the corn nor cotton crop will be a large one."

The editor of the Southwestern Farmer, also, in the same month says: "We have seen of the growing crop in all probability more acres than any other man in Mississippi. We have made particular inquiries, and also examined for ourself, and we have made up our mind that the corn crop is

more dependant on seasons than usual. Although it generally bears a good color and is clean, yet it is more irregular in height than we have ever seen."

From other sources we also learn, that in the northeastern section of the State, and west of the Tombigbee river, owing to the drought, the crop is "20 to 25 per cent. less" than in 1844. In the southwestern portion, however, west of Pearl river and south of the Yazoo river, it is thought to have been an increased crop—perhaps "15 per cent. more" than in the previous year. On the whole, we believe that the crop has fallen off in the State from 10 to 15 per cent. It is, however, a comparatively small crop in this State.

The early appearance of the corn crop of Louisiana appears to have been quite promising. Thus, in May. The Alexandria Red River Republican of the 12th inst. says: "We have heard that two or three of our planters have determined to try a corn crop this season, planting very little cotton. We think this step a good one. The crops will mature much earlier than those of the west, and will, of course, be the first in the market, with the chance of a reasonable price. The yield here to an acre is equal to that of any other portion of the country."

"The early corn is unusually fine; much of it is already in tassel. The late planting has been much injured by heavy rains."—*Planters' Banner, May* 24.

Again, in July—

Attakapas crops.—The Planters' Banner of the 12th inst. says: "The greater part of the corn crop is fast ripening. Within the last few weeks we have had an unusual quantity of rain for the season, which will occasion the loss of much fodder."

The Concordia (La.) Intelligencer states that "the crops in that neighborhood have been injured by the unfavorable weather."

In the northeastern part of the State, bordering on Mississippi, and reaching back to the river, we are informed that the corn crop was "20 per cent. heavier" on the alluvial lands, but lighter "on the uplands;" supposed to be an average of "15 per cent." Taking the whole State through, we believe that it will average 10 per cent. more than in 1844.

In Arkansas some complaint is made of the drought; but, on the whole, there seems to have been a good crop—perhaps ten per cent. more than in the previous year. More new land is brought under cultivation from time to time, which no doubt exerts some influence.

In a public journal it is said: "The corn crop in the Red river and northern counties has been greatly injured by the drought."

The editor of the Northern Standard mentions that the neighborhood of Clarksville is the only section of the Red river counties where there will be much corn for sale. He states, also, that "the corn in the Choctaw nation is burnt up."

Again, in June: "In Arkansas, every prospect of an abundant crop seems to be realized. As early as the 24th ult. the *corn* in some parts of the State was said to be 'waist high.'"

The crop in Tennessee—which State, according to the census, stands foremost among the corn-growing States—was fine. The papers of that State, in June, speak of the crop as "larger than for many years; extremely promising—bids fair to be an abundant yield," &c. From accounts re-

ceived since the harvest, also, it is estimated at 10 to 20 per cent. more. The average crop, probably, would equal if it did not exceed 15 per cent.

In Kentucky, also, the accounts are equally favorable. In the section of the State which lies west of the centre, the crop is stated to have been "20 per cent. more." On the south, also, more. In the central to the northeast, "very fine—20 per cent. more." Still further to the northeast, and east of this last, about the same advance; and in the southeast, "remarkably good —20 per cent. more." Taking the whole State, and making due allowance for overestimates, we believe we may safely put the increase of the crop over that of 1844, at 15 per cent. It may, perhaps, overgo this, but we deem it most likely to be correct to add only 15 per cent.

Ohio produces a large crop of corn, and is among the foremost in the amount furnished by the western States. We notice in one of the public journals a statement which shows the advance of the season in one part of the State, though we know not precisely to which section it refers. It is as follows: "We finished planting corn on the 26th April; this is a week or ten days earlier than usual in this part of Ohio." In the month of June, the Cleveland Herald thus notices a check given to the growth of this crop in that neighborhood: "The frost last week cut the *corn* in the lake counties so closely that only a part will sprout again, and the soil is so exceedingly dry and parched that farmers are at a loss whether or not to replant."—*Cleveland Herald.*

In the Ohio Cultivator it is stated, by the editor: "*Corn* is now advancing with great rapidity. We have just returned from a tour through much of the best corn region, and have no doubt that the crop will prove at least an average one." A letter from Butler county, addressed to one of the public journals, also says: "Notwithstanding the drought, the *corn* promises to be a fair crop." Again, in July: "The State Journal of the 5th instant reports the crops at the north and on the lake shore, where the drought has been most severe, as fast reviving, and likely to turn out more than an average yield; at least larger and better than last year." The Ohio Statesman of August 6, published at Columbus, contains the following mention of the appearance of this crop: "The editor has just returned from a short excursion into the country, and he was pained to see many cornfields that had been much injured by the grub-worm and other causes. There are, however, some fields that look well." In the same public journal, but of an earlier date, we believe, is given the statements respecting this crop in quite a number of counties, as they were furnished by persons who were acting as jurors at the session of a court in the place of its publication. We quote them exactly as we have found them in the above named journal—

"*Lorain county.*—Crop very poor; mostly cut off by frost.

"*Clermont county.*—First rate.

"*Lake and Starke counties.*—Prospect for corn good.

"*Highland county.*—Very good.

"*Richland county.*—Tolerable.

"*Tascarawas county.*—Promises well.

"*Meigs county.*—Looks well: bids fair to yield an average crop.

"*Fairfield county.*—Looks well.

"*Guernsey county.*—Looks well, though short—a favorable fall will make a full crop.

"*Hamilton county.*—Prospect of the corn crop generally good.

"*Warren, Butler, and Preble counties.*—Similar to Hamilton.

"*Green county.*—Corn good."

A correspondent of the American Agriculturist, under date of September 20, writes: "The fields on the Reserve, which, in the earlier part of the season, were exceedingly parched by drought, were looking somewhat better, and much of the corn was full eared and thrifty, but so backward that an early frost would nip most of it before sufficiently ripe to withstand its effects. So severe and long continued a drought has probably never before been experienced, or at any rate exceeded, in this or any other State." The following statement speaks of Aurora county. We apprehend that the township of Aurora must be meant. It shows the effect of the drought, however. The Cleveland Herald says: "Some of the dairymen of Aurora county have been into the southern portion of Ohio and contracted for some hundreds of acres of standing *corn* and stalks, on which to winter their cows. A gentleman from near Columbus also came into Aurora, and contracted to keep 500 cows through the winter at the rate of one dollar per month. Another gentleman was allowed to go into the yard of an extensive dairyman and select cows at five dollars per head. Two-year-old steers are selling at from three to five dollars per head."

The accounts we have received since the crop was gathered are, on the whole, however, encouraging. In the central section, including the important counties of Delaware, Marion, and Richland, the increase of this crop is variously estimated at from "20 to 25 and 30 per cent." North of these, and towards the northeast, it is estimated, on account of much more having been planted, as high as "40 per cent. better" than 1844. In Starke and Wayne counties it was "an average crop." Eastward, and bordering on the Ohio river and Pennsylvania, including Jefferson, Carroll, and Columbiana counties, it was a "fair average crop; equal to that of the previous year." South of the centre, on the Scioto river, "about 25 per cent. better," as there was a "short crop there the year before." In the counties of Perry, Morgan, and Washington, it was "nearly one-third better;" "the drought and late frosts seriously affected the corn crop in the early part of the season, but the latter part was more favorable." In the northwest corner of the State, bordering on Michigan and Indiana, it was "far better." Further to the east, however, and along the lake, there seems to have been a small decrease of perhaps "10 per cent." In the southwest part of the State, the crop is variously estimated to have increased from "20 to 30 per cent." The American Agriculturist for November contains a communication in which the following remarks are made respecting the corn crop in southwest Ohio. The writer is an experienced judge of agricultural subjects: "The corn raised here is universally the gourd seed, which, from long experience, is found to be the best producer, wherever warmth of climate and depth of soil are sufficient to develope and mature it. The yield, under ordinary cultivation, without manure, varies from forty to sixty bushels per acre; but, with manure and good attention, it will sometimes average one hundred. It is usually planted about four feet apart each way, with three or four stalks left in a hill. Some plant nearer, and leave fewer stalks together. It appears much thinner in the field than a luxuriant growth of northern corn. That planted on the uplands, on a lighter soil, is still more scattered, and from its great height appears thin and spindling. I doubt if many of the fields which met my eye out of the Miami and Scioto valleys would exceed twenty-five bushels per acre. This can hardly be profitable farming in a country where corn sells at from

fifteen to twenty-five cents per bushel, unless so far as it contributes to make out a rotation, and the stalks can serve a valuable purpose for fodder."

Taking the whole State into account, and comparing views with the various amounts in the different counties as given by the census for 1840, we find that, in the counties furnishing the heaviest crops of corn, there has been reported an increase during the past year; so that there has been a general advance, it is believed, of at least 20 per cent. on the whole crop in the State. We are almost inclined to put it at 25 per cent., but prefer to be within bounds.

The results of the corn crop in Indiana appear to be equally favorable. In the northern central section, above the Wabash river, and in the northwestern part of the State, it is believed that there has been "25 per cent. more." In the central part of the State more land was sown, and more industry applied, so that the increase is supposed to be "30 per cent." South from this last, also, there was an advance of "20 per cent.;" while an equal increase must be allowed for the southeastern section. Our informant here adds: "Owing to the drought in the early part of the season, enabling us to get the fields well cleared of weeds, and the rains setting in at least in time to make the crop, in some portions of the State the gain on the crop of 1844 is rated as high as 50 per cent., or more. It will be recollected that the crop of that year fell off very considerably in this State; and, in view of this fact, it may not be too high to estimate the average advance for the whole State, over the year 1844, at 25 per cent.

The early accounts of this crop in Illinois, and indeed its general progress, are most encouraging. A public journal published at Quincy, in this State, under date of May 7th, says: "The corn in this section is mostly planted; and, in some parts of the country, it is in so forward a state that the farmers were engaged last week in ploughing it. The showers of the two weeks past have had a most beneficial effect upon vegetation of all kinds." *June* 23.—We find the following statement in the Prairie Farmer, an agricultural journal of high repute at Chicago. The section embraced in this account comprises eight or nine counties. "The corn, it does one good to look at. For the last eighty miles much of the corn is from four to five feet high; and, had the weather been such that it could have been ploughed, it would now be mostly laid by. As it is, some must yet be ploughed to its injury, as the roots will be cut very considerably. The difference in the appearance of the corn from Cook and Dupage to Sangamon county, is truly wonderful. Without personal observation, one would hardly believe it." In one section, complaint is made of much damage having been suffered from the depredations of birds. Thus, the Ottowa (Ill.) Free Trader says: "The farmers in this vicinity are much troubled with the blackbirds, who visit the cornfields in such numbers as completely to cover whole acres, and destroy every hill of corn within their reach. Several farmers have replanted once or twice, and many at this time are going over their fields and repairing the damages of this troublesome little visiter."

A month later, the Alton Telegraph, speaking of the crop, says: "The corn never looked better, and the weather is very favorable."

In August, also, the condition of the corn crop is represented as being unusually good. We subjoin some of the notices respecting it which we have gathered from different papers:

"A gentleman, who is thoroughly acquainted with Illinois, and has recently

passed through the State, says that the crops of corn throughout are very good. Some of the corn is 18 feet high. Illinois had never before so valuable crops."

Again: The Alton Telegraph says: "We were told, a few days since, by a gentleman fully competent to form a correct opinion upon the subject, that the quantity of standing corn which may be seen from Mound farm, in Jersey county, under twenty miles from this place, cannot amount to less than 500,000 bushels. Nor is this all, or the best. From Mr. A. B. Davidson's residence, on the bluff, on the road from Alton to Edwardsville, and about seven miles from this city, there may be seen, without moving from the same spot, by looking only in two directions, fields of standing corn, the probable yield of which is estimated at 1,500,000 bushels."

The estimates made since the crop was gathered are similar. In the section of the State ranging along the west side of the Illinois to the Mississippi river, being the central tier of counties, it is judged to have been "50 per cent. more." In the central west, "one-third better" than in the preceding year. In other portions of the State, from "25 to 30 per cent. advance." This crop fell off largely the previous year. There has been a large quantity of public land sold here within the last eighteen months; and, on all accounts, we think we shall not overgo, if we fix the advance at 30 per cent. over the crop of that year.

From what we can gather of the corn crop of Missouri, we believe that it has been very good. Some mention is made, indeed, in the St. Louis New Era of May 21, of a severe frost a few days before, which nipped the corn in many places; but, as we advance towards the harvest, we find that the accounts are encouraging. Thus the Fulton Telegraph, in July, says: "The corn crop is unusually promising." The St. Louis Republican, also, during the same month, states that "the corn crop never looked better or more promising." A letter, also, in the New York Farmer, dated Gallatin, July 6, says: "The corn presents a splendid appearance;" "never more promising." So the Expositor, published at Independence, in September, says: "The crops of corn with us this year are most encouraging, and of the utmost abundance." We believe, therefore, in the absence of other sources of information, that the crop of corn in Missouri has been much superior to that of the preceding year—probably 25 to 30 per cent. better.

The editor of the Michigan Farmer estimates the corn crop for that State at "10 per cent. better" than in the year before. Such is, also, the view taken of the central eastern section, from Macomb to Huron county. It is said to have "suffered by the drought, but still exceeded the crop of the previous year." In the southwest, and along Lake Michigan, from the south to the centre, west, it is stated to have been "50 per cent. better." The extreme wet weather of 1844 is said to have injured the corn crop of that year, and this cause has not been felt during the past season. In the southeastern part of the State it is said that there is probably "three times" as much raised as in 1844. We believe, however, that, taking the whole State through, we may fix the advance at about "15 to 20 per cent."

In Wisconsin, also, and Iowa, there appears to have been a large corn crop. The Racine Advertiser, in July, says: "Corn, likewise, bids fair to be an average crop; the slight rains and warm weather for a week or two past having enabled it to recover from the blighting effects of the cold and dry weather of May and the beginning of June." The following statement respecting a fine crop in this Territory appeared in a public journal:

"In Columbus, Portage county, Wisconsin, S. W. St. John raised 192½ bushels of Dutton (12-rowed) corn to the acre. Some of the ears were over 13 inches long, and weighed 15 ounces." A writer in the Chillicothe Advertiser, speaking of northern Iowa, says: "It is fair to say that the cultivators of the soil in northern Iowa can raise corn that will average 50 bushels per acre; and it is certain that the corn crop here is a sure one." Compared with the crop of 1844, it is believed that there has been a large increase, as the season was favorable, and the increase of farming population has been very great.

From our preceding investigations it will be seen, that, while in some of the middle and southern States the corn crop has fallen off, yet, in the northeastern, southwestern, western, and northwestern sections of the country, there has been an advance, and the whole aggregate crop of corn for the United States amounts to nearly 417,900,000 bushels; which is about 2 per cent. less, compared with the previous year. We add here, also, several notices, which we have collected, relating to some large yields of corn in different States. More may be found in the appendix No. 3, where is given also a variety of interesting extracts from agricultural papers, &c., relating to modes of cultivation, &c. "The Chemung County (New York) Agricultural Society recently held its annual fair, the proceedings of which were very interesting. From the report of the grain committee, we learn that 5 specimens of corn were exhibited, all of good quality, averaging from 107½ to 123½ bushels per acre; of which, Wm. Hoffman, of Elmira, raised 123 bushels per acre; Josiah Townsend, of Southport, raised 121¼ bushels per acre; Nile Wynkoop, of Chemung, raised 113¾ bushels per acre; Samuel Leverich, of Southport, raised 107½ bushels per acre; John L. Smith raised 119½ bushels per acre." "An ear of corn, measuring sixteen inches long and seven inches in circumference, has been presented to the editor of the New Orleans Picayune. It was grown at Tiapa, in the southwest corner of the State of Tobasco, in Mexico."

"*Giant corn.*—Mr. William Crispin, of Marlborough farm, Great Timber creek, New Jersey, yesterday brought to this office some stalks of corn more than six inches in circumference, and 13 feet 9 inches in height. The reader may well manifest surprise, but the statement is nevertheless strictly true. Such immense stalks we never saw before. They excited no little attention, and were examined during the day by hundreds. Mr. Crispin informs us that the only manure used was about 80 bushels of stone lime to the acre. He thinks that if the crop had been intentionally arranged for 'a long crop,' and planted at certain distances, the produce would have been over 300 bushels to the acre. Surely, the worthy farmer alluded to deserves the premium for corn. We may confidently challenge the production of anything superior."—*Philadelphia paper.*

A new variety of corn is mentioned thus in the American Agriculturist: "*Peruvian corn.*—Edwin Bartlett, esq., of this city, has kindly given us five barrels of Peruvian corn, recently sent him from that country. It has the largest sized grains of any we ever saw before, and is quite a curiosity. There are two kinds—one called by the Peruvians *maiz blanco*, (white corn.) This is the Chancay corn, used for fattening pigs. It is a coarse, inferior article, but grows very rank and strong. The other kind, *maiz amarillo*, (yellow corn,) from Huacho, is large and fine, and is said to make the sweetest kind of bread. Mr. Bartlett informs us it is a great yielder. Any one wishing a quart or two of this corn for experiment can have the

same gratis by calling at our warehouse, No. 187, Water street. We are of opinion it will do best south of the Potomac, as it is a southern corn."

Large yield of corn.—The Highland (North Carolina) Messenger says: "We are informed by Mr. Alexander Porter, the manager of the farm of Thomas T. Patton, esq., that an acre of corn was planted on the farm the last season, with which it was designed to contend for the prize offered by the Buncombe county Agricultural Society, and that a few days since the corn was gathered and measured, and the yield was 113½ bushels! His farm is on Swannano river. Here, farmers, is an evidence of what can be done. Had the season been good, Mr. Porter has no doubt that the yield would have been 150 bushels."

The following statements respecting steeps for *corn* refer, respectively, the first to experiments made in North Carolina, and the last to others made in New Jersey:

"*An excellent mixture for corn.*—Lime, plaster, ashes, salt—equal quantities, well mixed. Prepare the ground well for planting—put a handful in each hill—drop the corn on the top of it, and then cover it with earth. It is good against the grub, preserves moisture, affords nourishment to the plant, attracts carbonic acid gas, and stimulates the soil."

"*Steeping corn, and compost.*—I observe that some of the farmers in this delightful section of country are trying many of the improvements of the age. A Mr. Webbe says he has tried steeping his corn and other grain in a solution of ammonia, and found much benefit from it. Last year, that grown from corn thus steeped was in harvest much sooner, and had larger ears than that planted dry in the same field. He also made a compost or mixture of one bushel salt, one bushel lime, one bushel plaster, and one bushel ashes, and put half a gill in each hill at the time of planting. This produced nearly one-third more corn than that alongside, planted dry, without any of the mixture. Otherwise, the land was manured alike."

The practice of smoking seed-corn has also been warmly recommended as a preventive against the depredations of birds, mice, &c. In a number of the Prairie Farmer, we find the following recipe given for this purpose: "Leave a few husks on the seed-ears, so that they can be hung up in the smoke-house and smoked with the hams; or hang them up in any dry place; and before planting dip the end of a stick in tar, set fire to it, and, holding it under the ears, give them a thorough smoking. I have tried this for three years, and have saved many times my subscription to the paper by it."

"*Large yield of corn.*—Lawton Turner, of Portsmouth, R. I., gathered, the present autumn, from a field measuring 8 acres 18½ rods, which he planted on the farm improved by Thomas R. Hazard, in said town, the following crop, viz:

593	bushels of shelled corn, worth (say) 80 cents per bushel -	$474 40
50	bushels ears of refuse corn, worth 15 cents per bushel -	7 50
20	tons of stalks and fodder, at $4 50 per ton - -	90 00
3	large ox-cart loads of Swede turnips, 150 bushels, at 12½ cts.	18 75
5	large ox-wagon loads of sweet pumpkins, at $3 per load -	15 00
	Total - - - - - -	$605 65

"The field averaging 73 bushels 2½ quarts per acre of sound corn. One

selected acre, 13⅓ rods by 12 rods, yielded 89 bushels 18½ quarts. The ground had been used as a sheep pasture for the last four years. About 6 acres of it were spread over with coarse barn manure and sea-weed previous to ploughing last spring. About one acre was manured in the hill, and the remainder was not manured at all."—*Herald of the Times.*

In the Southern Cultivator we are furnished with an analysis of the southern corn, by Professor Shepherd, which it may be interesting to quote here, for the benefit of those who may not have seen it. He says: "One hundred parts heated to redness in a crucible, so long as a brightly burning flame was emitted, lost 81.05 parts. The completely charred residuum, on being ignited beneath a muffle, on a platina foil, until all the carbon was consumed, left 0.95 part, or less than one per cent. of an easily flowing clear glass. This ash has the following composition: silica, 38.45; potassa, (with traces of soda) 19.51; phosphate of lime, 17.17; phosphate of magnesia, 13.83; phosphate of potassa, 2.24; carbonate of lime, 2.50; carbonate of magnesia, 2.16; sulphate of lime and sulphate of magnesia, 0.79; silica, (mechanically present,) 1.70; alumina traces, 0; loss, 1.65; total, 100.00. Omitting the silica as an unimportant loss to the soil, and the carbonic acid, which is a product of the analysis, we have, in every one hundred parts of the ash of the Indian corn, the following important organic constituents: Potassa, 20.87; phosphoric acid, 18.80; lime, 9.72; magnesia, 5.76; total, 55.15. That is to say, for every 1,000 pounds of Indian corn sold from an estate, the land is robbed of 9½ pounds of inorganic matter, whereof about 5½ pounds consist of principles of prime value to any species of crops."

It may sometimes be useful to know how to estimate the amount of corn in grain, contained in a crib or storehouse, while it is still in the ear, and we therefore give a statement relating to this subject, which appeared in an agricultural paper at the south.

"The following rule for ascertaining the quantity of shelled corn in a house of any dimensions is by William Murray, esq., of South Carolina, and was read before the St. John's Collection Agricultural Society, and communicated by them for publication in the Southern Agriculturist:

"*Rule.*—Having previously levelled the corn in the house, so that it will be of equal depth throughout, ascertain the length, breadth, and depth of the bulk; multiply these dimensions together, and their product by 4; then cut off one figure from the right of this last product. This will give you so many bushels and a decimal of a bushel of shelled corn. If it be required to find the quantity of eared corn, substitute 8 for 4, and cut off one figure as before.

"*Example:* In a bulk of corn in the ear, 12 feet long, 11 feet broad, and 6 feet deep, there will be 316 bushels and $\frac{8}{10}$ths of a bushel of shelled corn, or 633 bushels and $\frac{6}{10}$ths of ear corn; as, $12 \times 11 = 132 \times 6 = 792 \times 4 = 316.8$; or, $12 \times 11 = 132 \times 6 = 792 \times 8 = 633.6$. The decimal 4 is used when the object is to find the quantity of shelled corn, because that decimal is one-half the decimal 8, and it requires 2 bushels of ear corn to make one bushel of shelled corn. In using these rules, half a bushel may be added for every hundred; that amount of ears results from the substitution of the decimals. The term "barrel of corn," so much used by southerners, means 5 bushels of shelled corn."

An experiment is related by Mr. B. P. Johnson, of Rome, in one of the numbers of the Cultivator, respecting the prevention of injury to the crop

from worms. He states that on ploughing up some sward land for corn in the spring, he found under the sod a great number of worms. Fearful lest his crop would be seriously damaged after it was ploughed, he sowed broad-cast about 1½ bushel of fine salt to the acre, and then harrowed and rolled the land. His seed he also prepared by soaking it in warm water for about 18 hours. He next dissolved 2 ounces of sal ammonia, and put it in the water, in which about a bushel of seed was prepared. He planted his corn 2 days after the salt had been sown. It germinated very quickly, was remarkably vigorous, and the plants grew luxuriantly. Not a single hill was found to be injured by the worms, though multitudes were in the ground; while a neighbor who had an adjoining field, and who planted his seed as usual, lost at least one-third of his crop by worms.

Respecting *steeps* for Indian corn, the editor of the Cultivator remarks: "He prefers muriate of ammonia, which he would use by dissolving in water, enough fairly to cover the seed, which may remain in solution 24 hours at a temperature of 60° to 70°. An ounce of ammonia, at an expense of about 2 cents," he says, "is sufficent for 1 quart of corn."

Dr. Webber, of Charlestown, N. H., according to the New England Farmer, dissolved a small piece of muriate of ammonia, 4 or 5 grains, in half a coffee cup of water, and threw into the solution a handful of corn, which he allowed to remain 4 or 5 hours, and then planted it. He planted side by side other corn, not soaked, with that which he had thus prepared, and the soaked corn produced much the largest yield—generally one-third more. The land is stated to have been light and dry; and, for several of the experiments, the poorest spots were selected on purpose. The corn suffered from drought, but in all cases the soaked corn was decidedly the best.

Others, however, have made trial of steeps to no advantage, as appears by the following:

In a communication in the New England Farmer, an account is given of some experiments in soaking seeds in a composition of nitrate, sulphate, and muriate of ammonia, and nitrate of soda and potash, and which, when applied to corn, does not seem to have been equally successful. When steeped 100 hours the corn vegetated poorly, but when steeped 140 hours it lost its power of vegetation. After various trials, 80 hours was fixed on as the proper time, and three rows of steeped corn, and three rows not steeped, were planted through a large field. But the corn that had been steeped, if anything, appeared to flourish less than that which had not been steeped. A few single isolated experiments are not sufficient to determine such a question.

In an experiment mentioned in an agricultural paper, it is stated that seed corn taken from the tip kernels of the ear produced only half as much as kernels taken from the middle of the ear, while those from the butts of the ear gave about fifteen-sixteenths as much as those from the middle. A number of interesting papers on the culture of Indian corn will be found in the appendix No. 3. The method of raising "a sod crop" of corn on the prairies, contained in Mr. Ellsworth's account of prairie cultivation, (appendix No. 1,) is one which will interest many of our western agriculturists, and may perhaps be tried with success on some of the rich level lands in other sections of the country. The experiments of Messrs. Geddes, Young, Underhill, Darling, and others, mentioned in appendix No. 3, deserve the attention of the planters and farmers of our country.

The new variety of sweet corn for the table, obtained by Mr. Darling,

will be valuable to gardeners, &c., who furnish the markets of our large cities.

The importance of subsoil ploughing for this crop is evidenced in the following extract, which we give from the American Agriculturist of November last:

"A farmer from Connecticut informs us that he has raised a field of corn during the past summer which he thinks will average 80 bushels to the acre, and that he selected half an acre of the best, from which he gathered 134 bushels of ears, all sound and well filled out; that while his neighbor's corn adjoining was withering with the drought, his was luxuriant; and he attributes the whole of his success to subsoil ploughing. Another important fact stated by him was that the whole expense of planting, cultivating, and harvesting, after the ground was ploughed, did not exceed $3 per acre; that he did not touch it with a hoe, but worked it with a harrow and cultivator, and those few weeds that were not reached with these about the hills were pulled up by hand before going to seed."

In the March number of the Cultivator (1845) is given an account of an experiment made by Mr. Charles Colfelt, of Pennsylvania, in 1844, who, by the use of a peculiar compost of his own preparing, secured a large crop of corn. He states that he took 25 bushels of leached ashes, 10 bushels of plaster of Paris, 16 bushels of lime, and about 50 bushels of fine sheep manure, mixed the whole together on the barn floor, and dissolved the lime with beef and pork brine. After thoroughly mixing the compost, the heap looked like gray plaster. He then put one handful of this preparation in a hill of corn, until he found he had not enough to go over his whole 12 acres. He then reduced the quantity to one handful for two, and even three hills. His field was the poorest on the place, and he was told not to expect over half a crop of corn. It had been in wheat, and laid out one summer without clover; so that the prospect was not very encouraging. He adds, that some of his neighbors rather quizzed him about his compost, but were amazed when husking and hauling-in time came. The corn grew surprisingly. It was very tall; and although he says the cut worm and blackbirds worked on it to such a degree that he had to plant one-third of the field over again before the 20th of May, yet the crop was as good as any in the neighborhood, if not better. He gathered 26 wagon loads of 70 bushels each; being 1,820 bushels, or 151 bushels to an acre. Some of the ears he states were so high that a man six feet tall could not reach the top of the ears of corn. The kind of corn planted was the large and small yellow, and was all hard. Where the handful of compost was put was the best corn; and, as the quantity was diminished, the difference was readily perceptible in its appearance.

The Farmers' Cabinet of June, 1845, contains a letter from Henry Cazier, of Newcastle, Delaware, which recommends ploughing in September for corn. He states that it is a remedy for preventing the worm from destroying the young corn. His statement is as follows: "In this county the heart-worm and the wire-worm have made great destruction in the corn for the last ten years. I have accidentally found out a remedy that has twice succeeded in preventing the worm from destroying the young corn. In September, 1842, I ploughed a part of a clover sod for wheat, but the great drought prevented my finishing the field, so that I concluded to put the clover sod field in corn in the spring of 1843; the part ploughed in

September, 1842, escaped the ravages of the worm, while the land alongside, ploughed in the spring of 1843, was nearly all taken by the worm; this induced me to try again, which I did in the month of September, 1843, with the same success as before stated. To plough in November or December will not, as I believe, be of any use whatever as a preventive against the worm. I have known a field part ploughed in September, part in December, and the residue in March following, with the following results: The first escaped the ravages of the worm; the second and last were both destroyed in greater or less degree—all in the same field. Now, it is worth a fair trial; and, if September ploughing will prevent the destroyer, it will save the farmer much trouble and loss. It has succeeded in three instances, to my knowledge. The reason of which success, I leave for others better qualified to ascertain. The facts are worth attending to, as it may save many bushels of corn to the farmer. * * * * The foregoing observations remind the editor of a fact which occurred some eight or ten years ago. He ploughed about one-third of a field of fourteen acres for corn, very late in the autumn; the plough was then stopped by the frost, but the weather being remarkably mild for a few days in the second month, the plough was again started, and some four or five acres more were ploughed, when the cold weather again suspended operations. The remainder of the lot was not finished till the latter part of the fourth month, just before planting time. One-half of the field was limed with thirty-five bushels to the acre; the other half had no manure. The *cut-worm* was exceedingly troublesome all over the field. There was no perceptible difference in its ravages, either where the ground had been ploughed at different periods, or where the lime had or had not been applied. The corn was replanted and replanted."

An experiment in the culture of Indian corn was made by Judge Clark, of Waterloo, New York, in which a large crop (140 bushels of sound corn to the acre) was raised on a peaty swamp. The writer, who furnishes the account to an agricultural paper, says that the farmers predicted, that if the season should be wet the crop would be drowned; if dry, the muck would dry up and the corn wither. He says, however, that on going over the field one morning early, after the second hoeing, and the ears had commenced forming, in the height of the drought of last summer, instead of finding the soil dry and thirsty, the whole loose peaty mass was full of moisture. He attributes it to the hydrogen of the decomposed mass during night having united with the oxygen of the air, and thus having formed water, as well by capillary attraction as by chemical affinity. In a less porous soil, the union he thinks could not have taken place in the same way. If the peaty soil, too, had not been in a fine state of decomposition, the same result would not have occurred. If the season had been wet, the ditches would have prevented the crop from being drowned; but the decomposition not being as rapid for want of the heat of the sun upon it, the crop would probably have been ruined—not from its being overflowed, but as the union of the two gasses above mentioned could not have taken place from want of preparation in the peaty soil to evolve the hydrogen. The experiment is an interesting one, whether or not the theory advanced to account for the success be the correct explanation.

Mr. A. D. Coulter, of Herriotsville, Pa., also communicates to the editor of the same paper for January, 1846, the result of an experiment which he

made last season in drilling Indian corn, by which it would appear that this method deserves more attention than it has received. He made his rows three feet apart—put two grains fifteen inches apart in the row. On three acres he raised 369 bushels of ears. Some of his neighbors prophesied a failure, but were much astonished to find the result so entirely different from what they had expected.

Corn and potatoes in alternate rows are said, by a correspondent of an agricultural paper, to produce as much corn as if every row was corn, and half as many potatoes.

The *level* cultivation of corn is recommended in an essay on the cultivation of this product, read before the Agricultural Society of Fayette county, by Mr. John Wray, and published in the Somerville Reporter, Tennessee. He commenced this method of cultivation about twenty-five years since; and as he has found it to answer well, he still continues the practice. He uses no plough, but simply works his ground over with what he calls a *rake*, which mellows the soil and cleans the surface. He ploughs his land in October and November six to eight inches deep, and buries all the vegetation, and plants his corn from the 10th to the 25th of March; laying off the rows $4\frac{1}{2}$ feet each way, and leaves three stalks to each hill. He thinks the reason why some farmers do not succeed in the use of the rake, is because they do not plough their land, but only scratch it over at first, and the grass is not killed in its germ; but they do not use the rake till the land is overgrown, and then abuse the rake because it will not do all that was promised. This method of cultivation, as is obvious, can only answer in light, warm, and mellow soils. The editor of the Cultivator recommends the use of a light, narrow shovel plough, and in some soils a harrow will be found sufficient.

The cultivation of Indian corn for fodder, while green, has been alluded to and recommended in former reports. Some examples have been heretofore given of great productiveness obtained by sowing broadcast. The attention of many of our agriculturists seems to have been recently turned to this subject.

In appendix No. 3, we have quoted from the New England Farmer the statement of Captain George Randall, of New Bedford, Mass. It will be seen that he estimates the corn fodder taken from 2 $\frac{32}{160}$th acres equal to fifteen tons of the very best English hay. On the amount thus obtained he fed *twenty cows in milk, or in calf dry*, one heifer over two years old, two stock bulls grown, and five spring calves, for seven weeks and five days. This he states was all the green fodder his stock had, except what they could pick up from a pasture, burned up, in which they had run during the season. In five days after feeding on corn fodder, he says his cows increased their milk one can full, or ten quarts. We have ourselves had the pleasure of hearing from Captain Randall, in person, the confirmation of his whole statement as published, and his full confidence in the value of the green corn crop as fodder for stock of all kinds.

Another statement which is given in an agricultural paper mentions the planting of an acre of corn for fodder eighteen inches apart one way, twelve the other, and three kernels to the hill. The product was five tons of well cured stalks and fifty-four bushels of corn; the land was never manured; it was a clay loam, interspersed with granitic boulders, and quartz, and limestone. The estimate of expenses as given is as follows:

5 tons of stalk, worth this year $7 per ton - - - -	$35 00
54 bushels of ears of eight-rowed corn, at 25 cents - -	13 50
Total -	48 50
Deduct the cost—	
1 bushel of seed; planting, hoeing, cutting up, husking, stacking stalks, and use of land - - - - -	17 44
Net profit -	$31 06

The subject of *corn-stalk sugar* will be considered when we come to speak of the sugar crop.

The cultivation of *broom corn* has been mentioned in some former reports, and the use of the seed for feeding sheep spoken of. Confirmatory of this, we here subjoin a few remarks from the Massachusetts Ploughman: "The seed is excellent to fatten sheep. Albert Hibbard, of North Haddam, tells us that he makes use of the seed of his broom corn to fatten sheep; that they are very fond of it, and will fatten better on this than on Indian corn. Broom-corn is raised in great quantities in the river towns, where the brooms are made up and distributed to all parts of the country. We have often raised the corn for the sake of the brush; but we have never made much account of the seed, though we think it has seldom been converted into meal for hogs. Mr. Hibbard thinks the broom-corn seed more valuable for sheep than oats, or any grain, pound for pound." A correspondent of the Cultivator for November, 1845, in reply to a request for information on the culture of this plant, gives the following directions, which, we presume, will be acceptable to many farmers; as more attention has lately been turned to this subject in some parts of the country. "I am not prepared to give satisfactory answers to your correspondent on the subject of broom-corn, in every particular, but will briefly state that we have, the past summer, had about 35 acres under cultivation—about one-half on the Mohawk lowlands, (or flats,) which is the soil generally preferred; the balance adjoining, on a gravelly soil. On account of the extreme drought, the low ground has done much the best. 2d. *As to profits*, compared with other crops, much depends on the success you may have. Some seasons it does much better than others; the past has been too dry to give a good large brush; but with us the seed has been an extraordinary crop, averaging nearly or quite 50 bushels to the acre, and most of it very full and heavy, weighing 31 pounds to the bushel, and is excellent for fattening hogs. They eat it greedily, and thrive on it as well, if not better, than on Indian corn. An acre of good broom-corn should yield from 400 to 600 pounds of brush; and the seed, when good, is worth in its rough state as much as oats for feed. I have now on hand enough of prime seed to plant 200 acres, and can supply your correspondent with any reasonable quantity at the lowest market price. My seed is the largest and best I have ever seen. A letter directed 'J. D. F. West, Schuyler, New York,' will be attended to. As to the query 'Will the increased production be likely to overstock the market?' Like every other product of the soil, there may be an overstock some years more than others, but thus far the demand has kept up with the product."

To show the increasing value of this culture, we also subjoin a short article, taken from the Ohio Cultivator, and another from the St. Louis New

Era: "In confirmation of what was stated under this head, in the Cultivator of May 1, we find the following in the Marietta Intelligencer respecting the extent of the business in the Muskingum valley: 'Last year L. and S. Temple, of this place, commenced in a small way, for the purpose of testing the feasability of the enterprise, the manufacture of corn brooms. They obtained the planting of a little more than 100 acres of broom-corn; and, as the season was favorable, obtained a good crop, which they worked into brooms and broom-brushes here. They gave constant employment to 10 or 12 hands, and, in the course of last season, made 50,600 brooms and 4,000 brushes. This year they have contracted for the planting of 400 acres of broom-corn. Mr. L. Temple is also purchasing, and will pay good prices for, broom-corn to export. We are glad to notice all enterprises of this kind, and most heartily wish all engaged in them the success they deserve. Morgan county, we are happy to know, is doing a good business in broom-corn—for export, we believe. Mr. Asahel Pomeroy, of Windsor, in that county, has 300 acres planted, and is contracting for corn planted by others.'"

In the Ohio Cultivator of May 12, 1845, we find the following:

"*Broom-corn culture in Ohio.*—This article is becoming quite a staple product of the rich bottom lands of this State. From present appearances, it is likely that not only all Yankeedom, but England also, and perhaps the 'Celestials,' will soon be supplied with those important implements of household economy, brooms, from the Buckeye State.

"The most extensive operators in this new business are three brothers, named Eaton—young men of great enterprise and intelligence—natives of this State, and possessing all the necessary qualifications of genuine Yankees. One of them now resides in the 'great metropolis' of England, where he has established an extensive manufactory of brooms, the materials for which are all sent over from this country; and, in an unmanufactured state, are admitted free of duty. The demand there is almost unlimited, so that it is anticipated a very extensive and profitable business will be done. Another of the brothers resides near this city, (Columbus,) and is now engaged in putting in five or six hundred acres of the rich Scioto valley land, (belonging to the Messrs. Sullivant,) which is spread out several miles in width, in full view from the window by which we are writing. He raised about three hundred acres on a portion of the same land last year. The other brother resides at Circleville, twenty-five miles further down the Scioto valley, and is there putting in four or five hundred acres more; besides which, they have numerous contracts with farmers for smaller lots, to be grown for them, and delivered at their presses when harvested. All this is intended for shipment to the brother in England, next fall.

"In addition to all this, we learn that there is as much more land devoted to this crop in the valleys of the Muskingum and the two Miamis, the product of which is mainly designed for the New York and New England markets. We shall, on other occasions, give particular accounts of the culture and profitableness of this product, and the success of the foreign branch of this novel enterprise."

Brooms.—The Northampton Courier states that "Mr. J. D. Brown, of Hatfield, has *sixty acres* of broom corn under a high state of cultivation, at Fredericksburg, Virginia. It is now being cut, and the brush is to be manufactured into brooms by him, at Baltimore."

Again—

"For the Farmer and Mechanic.

"*Schenectady, August* 28, 1845.—The farmers in this vicinity are cutting their broom-corn. They scrape the seeds off while it is green, and then dry it under sheds or in kilns. The seed is lost, but the brush is enough better to pay the loss of that. One gentleman told me to-day that he had one hundred and thirty acres in broom corn; and another, near by, has two hundred acres, and it never looked better. A pound of broom-corn is worth as much as a pound of pork in Ohio. A little west of this, I see farmers are getting in their fall crops in true New England style; plough the ground well, and put a moderate quantity of fine manure or compost upon the furrows, and then drag it in with a sharp harrow, before putting in the seed. In this way you are more sure of a good grass crop to fallow the grain. The ground is left more open, and the roots take a deeper hold, and of course last longer. Yours, E. P. W."

"*A new article of trade.*—We noticed landing 25 neatly packed bales of broom corn tassels, grown up the Mississippi river, and a portion of a crop which will amount to over 100 bales. The 25 shipped here have been sold in New York, to arrive at five cents a pound. If sales can be effected at this rate, we should think it to be a profitable crop, as the culture is very simple, and requires but little outlay either of capital or labor."—*St. Louis New Era.*

The Cultivator for January, 1846, states that "the fine interval lands of the Messrs. Sullivant, near Columbus, have, as usual, been covered with corn this season, on 400 acres of which has been grown broom-corn, by Mr. Eaton, of Chillicothe, who has also, this season, grown the same crop near Circleville and Chillicothe; in all to the amount of 1,000 acres, which has been very nicely prepared, put in bales, and pressed, and has already gone forward to be shipped to England, where the owner has workmen employed in manufacturing it into brooms."

Another application of broom-corn is suggested, in an extract which we present, taken from some public journal. Should this prove successful, it might render this product one of still greater value to the agriculturist:

"A specimen of paper made from broom-corn stalks has been shown in Philadelphia. The Philadelphia Inquirer alludes to it as an excellent article, remarkable for toughness, flexibility, and body; and (another important matter) offered at a very low rate. The manufacturers deserve credit for their enterprise."

POTATOES.

The potato crop of the last season has again been subjected to the same disease which so greatly lessened it in the previous year. To whatever cause it is to be attributed, yet the extent of its influence has been greater, for it has made its appearance in sections of the country which had been before free from the same. The precautions suggested in the former year may have aided in checking the evil to some degree; but the whole amount of decrease is fearfully enlarged in those regions generally affected heretofore.

The New England States have again been among the principal sufferers. The accounts from first to last, since the period of its development, have been more unfavorable in Maine. The public journals and agricultural papers have been uniform in declaring that there has not been more than

half a crop. From the fact that an extension of the starch factories created a greater demand for potatoes, there have been many more planted; but a great many have been destroyed, either in the ground or after they were gathered and stored. Thus the Augusta Age, in the centre of the State, in September, says: "We regret very much to learn, from all parts of the country, that the potato crop is almost entirely destroyed. In a recent trip in Lincoln county, we were informed by many of the farmers that they should be hardly able to obtain enough potatoes in a sound and healthy state to replace the seed of last spring. The vines or tops died some weeks ago, and, on digging, the potatoes are found to be very small in size and few in number; and what is still worse, those that are found prove to be much diseased, and soon rot and become unfit for use. The result must be that this State, from which an immense amount of the first quality of potatoes have heretofore been annually exported, will hardly produce enough for the consumption of its own citizens." Again: "The Eastport Sentinel states that it has been estimated that there were shipped from that port last season 19,620 barrels of white blue nose potatoes, and that the quantity shipped direct from Calais, Robbinston, Perry, Lubec, and Pembroke, would make the number of barrels exported rising 40,000. It is now supposed that the quantity to be sent to market will not exceed 5,000 barrels, as very few farmers in the neighborhood will have more than will answer for seed and their own consumption." So, in October—"We are sorry to state that the failure of the potato crop in this vicinity is much more extensive than last year. Many fields do not yield the quantity planted, and almost all are more or less affected. From present appearances, there will not be half of an average yield; certainly not, unless the process of decomposition is soon stopped, which may be the case by cold weather. The fall season has been unusually mild—no severe frost until within the last week."—*Calais* (*Me.*) *Frontier Journal.*

Another paper says: "From last year's crop, it is estimated that the loss by rot this year, in Maine, cannot be less than $1,230,000, or more than two dollars to every person in the State." By some we are informed that there was not "one fourth" as large a crop as in 1844. In many sections they failed entirely; in others, the quantity raised was not over what was planted. As the prevalence of the cause was so universal in the State, we think that we shall not be far out of the way in fixing the decrease at an average of 30 per cent.

In New Hampshire, in the southeastern and eastern sections of the State, the injury was probably as much as "20 to 25 per cent.," as compared with the crop of the previous year. A correspondent writes from this part of the State, that "the crop was much injured by the rot, which has caused much fear as to increasing the crop; it has generally been the case that potatoes were grown where corn would not succeed, and the quantity raised has been on the increase; but of late, the people have come to a pause on the propriety of increasing the crop." On the Connecticut river, in the southwestern section, it is said to have been, on the whole, a fair crop. "Many fears have been entertained for the potato crop on account of the drought, and the rot which prevailed so extensively last year. Happily, these fears have been realized in neither respect." If we compare the state of the crop with the census in 1840, we find that there has been considerable falling off in portions of the State which are extensively engaged in

raising potatoes, so that the average decrease for the whole State cannot have been less than from 15 to 20 per cent.

In Vermont, from every section we hear the same complaint. Thus, it is said: "We are sorry to state that the failure of the potato crop in this vicinity is much more extensive than last year. Many fields do not yield the quantity planted, and almost all are more or less affected. From present appearances there will not be half of an average yield; certainly not, unless the process of decomposition is soon stopped, which may be the case by cold weather. The fall season has been unusually mild—no severe frost until within the last week."—*St. Alban's Messenger.*

Lower down, and in the northeastern section of the State, we are informed, that owing to the rot the crop has fallen off at least "25 per cent." The same, but to a less extent, was the case in the southwestern portion of the State, the potatoes having suffered much from the rot since they were harvested. The whole decrease may have been from 15 to 20 per cent.

The disease very much injured the potato crop in Massachusetts. In the northeastern section of this State, a good judge on the subject says that a large portion of them were diseased, and thinks that they fell off "40 per cent." Lower down, in the central eastern section, the decrease is estimated at from "25 to 30 per cent." In the interior we are told that the disease was thought to be less fatal than last year at the time of the harvest; but since then, they have shown more general disease than last year. In the western part of the State the crop is considered "one third less" than that of the previous year. Our informant here adds: "The yield of the potato crop was full an average, and the cause of the diminution in quantity was in consequence of the farmers not planting as many as usual. The disease among the potatoes called the rot was very fatal to the crop last season. They were affected by the same disease this year. It did not commence so early this season as the last, but its ravages are still going on in our cellars. Last season, after cold weather, there was not much complaint." The whole diminution of the crop cannot be less than 25 per cent. as to valuable product, though the number raised may, in sections, have been actually more. There was, likewise, from the drought and rot, a decrease in Rhode Island and Connecticut of not less than 15 or 20 per cent.

The accounts from the various parts of the State of New York represent the potato crop as suffering from the drought early in the season, and subsequently from the rot. Thus, in June, a Batavia paper says: "Early potatoes are used up; but, in consequence of the frequent showers with which we have been recently visited, late potatoes will probably be sufficiently abundant." In August, however, we are informed respecting the crop in the western part of the State—"The potato vines give evidence of the work of the worms, or the disease that was so destructive last year." In the vicinity of New York, in July, it is said: "The early planting has turned out better than was expected; but fears are entertained for the fall crop. Since the seed was put in the ground in June, the drought has been unparalleled. Unless we have speedy rains, we shall have even a greater failure than last year." In August, from the same authority, we learn that "potatoes are nearly ruined. They have revived, but still the appearance is unfavorable, though there is time for improvement." The crop in that region turned out better than in the preceding year; but, owing to the rot afterwards, it decreased from "10 to 20 per cent." Further up the river, the rot also lessened the number gathered. In Albany county the loss was

from "15 to 20 per cent." The same was the case proceeding to the northern sections of the State. In Rensselaer county and vicinity, the crop is thought to have fallen off "25 per cent." The same in Washington and Essex counties. The following is from the county of Washington: "The potato crop has suffered by the rot, which has really become fearful. Every farmer, almost, has been obliged to take them from the ground when buried, and it is probably below the truth to say that fully one-third of the entire crop is lost, and the remainder greatly injured. In Jefferson county, also, the drought is thought to have reduced the amount gathered "30 per cent." In the Mohawk valley, the decrease is estimated to have been still greater. Southeast of this, however, we are told in Otsego county "the crop of potatoes is far better, for the reason that the disease which seriously affected them last year has not made its appearance this year." A similar account is given respecting Schoharie county: "The crop of potatoes is probably double in value that of last year, for the reason that the disease which was so ruinous to potatoes last year has not affected that vegetable much, if any, this year. It is supposed to be "25 per cent. better." Further west, also, the crop was good. This was the case, we are told, in Oneida, Madison, and Oswego counties—"15 or 20 per cent. better." Less were planted in Onondaga county, and the disease prevailed to a considerable extent. In Cayuga and Cortlandt counties, likewise, the potato crop fell off so much that there was not more than "one-fourth or one-half a crop." In the more southern sections, however, the increase is estimated at from "15 to 25 per cent." This was the case in Yates and Chemung counties; "last year potatoes were very much injured by the rot, but this year very little." A similar increase is supposed to have been the result of this crop in Seneca and Wayne counties. In the western counties, on the lake, however, they probably fell off from "20 to 25 per cent.;" and in the extreme northwestern part of the State the decrease is estimated to have been not less than "one-third or one-half." In the southwestern section the rot was not so destructive—perhaps not more than "10 per cent." Taking the State census return as the basis of calculation, therefore, the falling off in the crop will not appear so great, as it may not exceed 10 per cent. for the whole State. Some of the heaviest potato raising counties did not exhibit so great a decrease as others.

The drought and rot also affected the crop in New Jersey, reducing it in some sections "25 per cent.;" in others, perhaps not quite so much. Altogether, however, it seems to have been a short crop—perhaps 15 or 20 per cent. less.

From every section of Pennsylvania, also, we are informed that there is a falling off of this crop. In the southeastern counties, including Lancaster and Chester counties, and the vicinity of Philadelphia, the decrease is variously estimated at from "15 to 50 per cent." In Bucks county and Lehigh, also, on the east, there was a falling off of perhaps "25 per cent." A larger decrease took place in the counties on the Susquehannah, bordering on Maryland—in some cases, thought to be equal to "50 per cent. less." In the northeastern section of the State there was a decline, but perhaps not exceeding "10 per cent." The same was the case, also, in the northwestern central counties. On the whole, there appears to have been a decrease of 20 to 25 per cent. average for the whole State.

The drought is also the subject of much complaint in Maryland, as affecting the potato crop. In the northeastern section of the State, the falling

off is estimated to have been as much as "50 per cent." The rot is likewise stated to have done much injury in the same section. A portion of the potatoes raised in Maryland are sweet potatoes. So far as we can ascertain, this disease did not affect them. The average decrease may be fairly put at about 20 per cent. for the whole State.

In some parts of Virginia the potato crop was much cut off by the drought. We do not, however, recollect any complaint of the rot; probably because the greater portion of the crop consists of sweet potatoes. In the central region, east of the Blue Ridge, they suffered greatly, and, we are told, were almost an entire failure. The same was the case in the section bordering on the Kanawha and its branches, (western central,) where the loss is believed to have equalled 25 per cent. In the northwestern counties of the State, however, there was a slight increase. The decrease for the whole State is estimated at 20 per cent. Though free from the rot, yet the potato crop of North Carolina fell off largely, varying, in the different sections of the State, from "25 to 30, and even 50 per cent." The drought is assigned as the cause of this loss. In South Carolina, also, the accounts are not less unfavorable; and, in some cases, as in the region of Spartanburg and the adjoining counties or districts, where the drought seems to have been most severe, the decrease is believed to have been "three-fourths" of the whole crop. In others, as in the northwest part of the State, it is fixed at "25 per cent.;" in the northeastern, towards the central, "40 per cent.;" and in the east central, bordering on the coast, about "20 per cent." The decrease may, therefore, have been about 25 per cent. average for the whole State. In Georgia, in the portion of the State lying in the northwest corner, there was as abundant a crop, both of Irish and sweet potatoes, as is usual. In the central, west of the Ocmulgee river, we are informed that there was not "one-fourth of a crop," and the drought affected them seriously in other sections of the State. The decrease was probably about the same as that in South Carolina. The falling off in the central part of Alabama seems to have been nearly "one-half;" while, in some other portions, it was less affected by the drought, and in others even an increased quantity was produced. The whole decrease was probably 10 to 15 per cent. The potato crops of Louisiana, Mississippi, and Arkansas, are but little noticed in the agricultural journals; and our other sources of information are so scanty that we can scarcely venture a conjecture, but probably there should be some allowance made for the drought; yet, even taking this into consideration, we cannot suppose that it varied much from the usual average crop. There was, we believe, a slight increase in Tennessee—in some sections perhaps as high as "10 per cent." Such is the estimate of those who have had an opportunity of judging. In Kentucky, in the northeastern section of the State, and thence towards the centre, there is complaint of the drought, and the decrease is estimated at from "20 to 30 per cent." In the southeastern part of the State, by some there is supposed to have been an increase of "10 per cent.;" while, in the interior of the State, towards the west, it did not differ much from the crop of 1844. Neither of them, however, could be called good crops—perhaps a slight increase.

The early prospects of this crop in Ohio were favorable. They are said to be "good—promise well," &c.

The Milan Tribune in August says: "Apprehensions begin to be felt as to the prospects of the potato crop, especially that part of it on sandy land. We have not made very general inquiry, but what we have made, and per-

sonal examination, convince us that this crop in danger. In examining a dozen hills where the tops seemed most thirsty, we found but one hill in which anything like patatoes was perceptible. Others gave the same report. Rain, and that soon, will be required to save this important vegetable."

In the north and northeast section on the Reserve, from the centre, from drought and disease the crop is thought to have fallen off "30 to 50 per cent." East of the centre, on the Ohio river and Pennsylvania, the decrease did not exceed, it is probable, more than "10 per cent." South of the centre, on the Scioto river, it was about "20 to 30 per cent." The rot was also felt in this section. In the southwest section of the State, on the Miami valley, it fell off, it is said, "25 per cent." West of this there was a slight increase—perhaps "10 per cent." In the central northern sections, including Delaware, Richland, Knox, and Licking counties, &c., it was better in the first named counties—perhaps "20 to 25 per cent." increase; in the latter the gain was not so large, as the rot was somewhat felt. In the northwest corner of the State "10 per cent. more," and about the same east, along the lake, towards the central north section. We believe that, taking the whole State, there was a falling off of perhaps 10 to 15 per cent.

The crop of potatoes appears to have suffered much from the drought in Indiana, and mention is also made of the disease, which does not seem to have prevailed there in 1844. In the north central section, above the Wabash river, and in the northwest part of the State, it is estimated to have been "25 per cent. less." In the central portion of the State a similar conclusion is drawn; while on the west of this it is thought to have fallen off at least "30 per cent." In the southeast section, where the blight is mentioned, there is perhaps a less crop by "20 per cent." Our informant, describing the blight which has affected them, says: "It first affects the vine just above the ground; it turns black and gangrenous, and the whole top dies for want of nourishment from the root. The potatoes are sound and good; but there are few, if any, with us, which have attained their full growth, owing to the death of the vine having occurred before the full growth of the potato could take place. We have not as yet been able to ascertain the cause of the disease which affected the crop on old, new, and manured ground, as well as that which was not." The whole crop of this State must have fallen off from 20 to 25 per cent.

In most parts of Illinois there was a considerable falling off of the potato crop. In the northwest and northeast sections it is variously estimated at from "10 to 25 per cent." In the central, west of the Illinois river, and towards the Mississippi river, it is thought to have been considerably better. Still lower down, towards the southwestern corner of the State, there was a decrease of "25 per cent." On the whole, probably there was an average decrease of from 10 to 15 per cent. for the whole State.

The following, from the Prairie Farmer for November, 1845, shows that the disease has made its appearance there:

"*The potato rot.*—This malady, which has been creating such dismay in the eastern States and over Europe, has made its appearance among us, and its ravages in sections of Will county are described as fearful. Some farmers out of 300 bushels do not harvest ten; and those which were harvested in good order are found in a little time entirely useless. When many decay together, the stench is intolerable."

In Michigan, with the exception of the southeast part of the State, there has been a decrease, varying, as estimated, from "10 to 30 per cent." The

editor of the Michigan Farmer places it at about "one third." On the whole, we believe the average to have been from 10 to 15 per cent. less. The appearance of the *rot* is mentioned by the Niles Republican, which states, "in Berrien and Cass counties hundreds of bushels have been put in the cellar dry and in good order, but have taken the rot, and been completely destroyed."

A writer in the Michigan Farmer, also, under date from Jackson, says: "Michigan has hitherto escaped nearly uninjured, but the present year the disease has prevailed with some virulence in certain neighborhoods in this and one or two adjoining counties. We have not heard of its appearance in other parts of the State."

The whole potato crop of the United States for 1845, including, of course, both common and sweet potatoes, is estimated to have been about 88,392,000 bushels. We have no means of ascertaining how many of these were sweet potatoes, but we presume as many as one sixth or one-seventh, if we may judge from the proportion of the States in which the crop was raised.

The *culture of the potato*, both the sweet and Irish, as it is termed, is an object of much interest to our country, and any suggestions on the subject from those who are well fitted to give them, will also prove of much interest.

In appendix No. 4 will be found several articles of value on these topics: The paper on the culture of the sweet potato, by W. Summer, of Pomaria, S. C., which we have taken from the Cultivator for February, 1845. Another short article, also, is given, which originally appeared in the Vicksburg Constitutionalist; and we have also added Mr. A. Vestal's method, as set forth in his pamphlet.

The following is an analysis of the sweet potato by Professor Shepherd. He says: "The tubers analyzed, though fresh from the market, were obviously drier than when first harvested. 100 parts of the thinly sliced tuber, on being thoroughly dried at a temperature of 200°, lost 58.97 per cent. of water. One hundred parts of the undried potato gave 1.09 parts, or rather over 1 per cent. of a whitish ash, or a bluish green color. Its composition was as follows:

Carbonate of potassa, with traces of soda	60.00
Phosphate of lime	14.57
Phosphate of magnesia	5.60
Carbonate of lime	5.39
Carbonate of magnesia	3.80
Chloride of potassium	4.60
Sulphate of potassa	4.35
Silica	0.70
Chloride of calcium, sulphate of magnesia and lime, alumina, oxides of iron and manganese, in traces, and loss	0.99
Total	100.00

One hundred parts of the ash from the sweet potato tuber contains, then, the following inorganic principles, which must have been withdrawn from the soil, viz:

Potassa	43.59
Phosphoric acid	11.08

Lime	10.12
Magnesia	3.80
Potassium	2.42
Chlorine	2.18
Sulphuric acid	1.90
Total	85.09

The articles on the culture of the common potato, also contained in the appendix No. 4, above mentioned, from the Indiana Farmer and Gardener—the one contained in Mr. Girdwood's letter to the Cultivator, and found in that periodical for October, 1845, on the potato culture in Scotland—and Colonel Clark's letter, &c. will amply repay the time and trouble of a perusal. We add here two short extracts from different agricultural papers on the same general subject:

"I noticed a method of cultivating potatoes which struck me as very good, especially on old ground. First, furrow the field both ways, and then plant in the check or cross of the two furrows; cover them lightly, yet deep enough to have them vegetate quick. As soon as the sprouts begin to crack the ground, go into the field, and from the cart put a shovelful of coarse or green manure on top of the hill; then plough between, turning the furrows together, and covering the manure. Always follow with a hoe, and see that the manure is well covered. As the rows run both ways, when it is time to hoe, plough contrary from the first time, and very little labor is required to hill sufficiently and keep the weeds down. The manure is as safe in this manner as it is heaped up in the yard or field to wait the fall crop. It is not exposed to the sun, nor is it as likely to heat and throw off the ammonia, and other properties essential to vegetation, as it would be in larger quantities or heaps. In digging the potatoes, and ploughing again for the grain crop, the manure is completely mixed with the earth. I go heart and hand for putting all manure into the earth as soon as it can be got from the farm, whether coarse or fine, especially in the spring of the year, instead of heaping it up to rot and waste through the summer. Mr. Demarest says he gets nearly double the quantity of potatoes from this method, to what he would without this manure. Coarse manure helps to keep the earth moist under it. I have seen potatoes vegetate and produce well lying only covered with straw, about six inches, and no earth over them.—E., *Passaic county, New Jersey.*"

"S. Widney, of Piqua, Ohio, informs us that he successfully cultivates potatoes on the following plan: Plant in hills, and when the potatoes are about an inch out of ground, take a light plough and run it so close to them as to cover them lightly with earth. When they get through this an inch or so, cross-plough them, covering up as before. This mode is stated to be equal to the best hoeing, besides being a great saving of labor. Mr. W. states that he has practised this mode for several years, and has never lost a hill, or had them at all injured by covering." Some remarks on this method of Mr. Widney, by Mr. Bickett, may be found in the appendix No. 4.

Mr. T. C. Hines, of Nansemond, Virginia, in the August number of the Cultivator, describes a mode of cultivation there practised, which he thinks may have a tendency to prevent the disease that has proved so destructive; but he does not say whether he is speaking of the common or the sweet po-

tato. He says: "In the selection of our land we prefer a light, sandy soil, without great regard to the richness of quality. This having been well pulverized, is drilled to the depth of from five to six inches, and from 1½ to two feet apart; at the bottom of these furrows, and at the distance of eight inches, are laid the potatoes, which we prefer being cut with from two to three eyes to a piece; the drills are then filled nearly to the top with the best littered stable manure, and a small portion of dirt is thrown on this so as to level the whole. The entire surface of the ground is then covered with leaves (we prefer fine straw) to the depth of from three to six inches. The advantages of the straw are obvious; by the use of it a more uniform moisture is produced, as well as temperature of soil, which is also kept perfectly free from grass and weeds, although no further attention is required, either from the plough or hoe, until the maturity of the potato, which for size and number I have never seen surpassed or equalled by those raised by any other method."

Mr. Robey, of Hopewell, Virginia, says, in the same periodical for September, "that he has been successfully breaking up a piece of sward land in the fall and spring, which he reploughs about the 20th of June. He plants the potatoes in pieces, a foot in the row, the rows four feet apart. When the tops are about six or eight inches high, he runs the plough close to the potatoes and throws the earth away, and then turns the earth immediately back and follows with the hoes. This is all the working they get."

As to planting in hills or drills, we are told, in an agricultural paper, that the Plymouth County Massachusetts Agricultural Society, in 1844, paid premiums to ascertain the best mode, and the following results were obtained:

"P. Bassett, of Bridgewater, raised in hills 363 bushels, in drills 425 bushels, per acre. Paul Hathaway, Middleboro', 331 bushels in hills, 396 bushels in drills, per acre. B. Hobart, 270 bushels in hills, 310 in drills, per acre."

Other statements as to the culture of the potato will be found interspersed also in the articles on *the rot*, in the appendix Nos. 5 and 6.

The question has been discussed in a number of journals, from time to time, respecting the advantage or injury of removing the blossoms from the vine. In the appendix No. 4, we have therefore introduced some articles on this subject; one from the London Gardeners' Chronicle, edited by Professor Lindley, the celebrated botanist; another, alluding to the same, in the Boston Cultivator.

Another question which is still mooted in the discussions of agriculturists is that of cutting or dissecting the potato tuber, or subdividing the plant. We also quote a statement on these subjects from a pamphlet by Robert Arthur. By dormant dissection is meant cutting in the autumn or winter, instead of spring:

"*Experiment on dormant dissection.*—In this experiment the seed was cut in November, and immediately stored in an old stable among peat mould; they were not so much diseased as the whole ones in spring. There were only four of the sets covered with blue mould, the rest being healed over bright and hard, and white. The blue moulded ones did not grow, but all the others grew vigorously, producing much taller plants and larger foliage than the former. The crop was later than by bleeding, dissection, or subdivision, and produced at the rate of 11½ tons per acre of larger and healthier potatoes."

"*Experiment on potato plant subdivision.*—In this experiment the seed

was preserved the common way, removed to a vinery in March, buried among mould, watered abundantly, and, when sprung to 6 or 8 inches, each large potato was subdivided into from 9 to 12 plants, having one rooted stem with a small set to each. These were dipped in puddle, and planted 10 inches apart, at an angle of about 45°, with the tops towards the east. Other experiments, however, suggest that the roots and potatoes should be exposed to the south, (or as near that point as practicable,) with the tops northward. The result of this experiment was, an earlier crop, by about 3 weeks, than by dormant dissection. The tops were regular, but not so vigorous. The potatoes were of very equal size; smaller, but much more numerous, than by either bleeding or dormant dissection. Although, by this subdivision, the peck planted fully double the length of the drill, on equal portions of the ground being cleared, potato plant subdivision yielded fully 13 tons per acre; that is, more than double of bleeding dissection, and 2½ tons more than by dissection."

In the Agricultural Village Gazette of W. Löbe, from which we have already quoted an account of Siberian rye, the *winter culture* of potatoes is recommended by Von Plotho and Franckg. The first, under date of April 1, 1845, says: "In spite of the severe winter, I have, on the 1st November, covered up potatoes with leaves only a foot high, and they have grown admirably, and are perfectly formed." The editor states that the specimen furnished him of these winter potatoes were indeed of so remarkable a kind, that it furnishes a strong recommendation in favor of the winter culture. The other correspondent says, that in the beginning of September, by way of experiment, he laid out a little bed in his garden, and planted half with white potatoes, and half with red ones, and covered them only slightly with earth. "The potatoes throve more rapidly and stronger than in the spring season." His business called him off, so that they were neglected till after a hard frost; in December (7th) the leaves were already nipped and dead. He then covered up the bed with alder leaves, and, by the middle of April, had the satisfaction of eating therefrom fresh good-tasting potatoes. The product of the red was greater than that of the white. He was so well pleased with his experiment, that he intended repeating it on a larger scale.

Speaking of early potatoes, the editor of an agricultural paper in Boston remarks: "A writer in the Maine Cultivator says that he planted the white blue-nose potatoes the last of April, and he had good-sized ripe potatoes on the 14th of July. We have tried many experiments to ascertain what potatoes are the earliest, (selecting seed from different sections,) and we have found the above kind the earliest of all, and, when used early, of the finest quality, being very good and mealy before fully grown. They do not usually grow large, nor yield well; but in the neighborhood of Eastport, Maine, owing to a peculiar soil or high manuring, they attain a good size; and large quantities of them are sold in this market, under the name of 'Eastport potatoes.'"

The use of the potato for *starch* has been steadily advancing in our country for some time; and, we doubt not, will eventually consume a fair proportion of the surplus crop. In one of the public journals we find the following statement, which is encouraging. It is dated some time in August last: "No less than 20 potato-starch factories are in progress of building in the county of Franklin. More than 50 tons of starch were made at the factory of Abiel Abbott, in Farmington, the last winter. A number of

starch factories are going up in the western part of the State."—*Thomaston Recorder.*

A fuller statement is also given in the Maine Farmer: "About 100 rods from the centre of Mercer village are 2 starch factories, located by a small stream, with a dam across it, which affords the necessary power to keep them in motion. One has been in operation but a short time; the other for some 2 or 3 years, we believe. They are doing a good business for the proprietors, and also for the farmers in the vicinity, who find a ready market for their potatoes, which, as a general thing, is as profitable a crop as is cultivated. The walls of these buildings are built of bricks, and the structures themselves are somewhat larger than we had anticipated, being, we should judge, about 50 feet in length, by 35 or 40 in width, and inside 3 stories high. The starch made is of first rate quality. It is principally taken to Massachusetts, where it is readily marketed, and consumed mostly in the calico and cotton factories. We are informed that one of these factories manufactured into starch the past season rising 1,8000 bushels of potatoes, giving employment to 6 or 8 men. During the summer months, after the potatoes are all ground, only 2 hands are required to a factory, they being employed in drying the starch that could not be dried during the spring, and in putting it into casks. The dry-rooms are large, on the 2d floor, and are heated by a huge furnace below. Starch factories are springing up all over the country. Three are under process of erection in Starks, at different points, and will be ready to commence operations the coming fall. There are now being completed, and being erected in Somerset county alone, ten starch factories. These will consume an immense quantity of potatoes; and farmers have made calculations accordingly, and planted largely. We heard one farmer say—who is himself interested in a factory, now in process of erection, either in Starks or Solon, we do not remember which town—that he had planted 15 acres of land in potatoes."

The disastrous results of the potato *blight* in Europe have called out the efforts of the scientific men, both in England and on the continent, to suggest modes of converting this fruit into flour, or farina. In the National Intelligencer, the correspondent from France furnishes the following account of a mode discovered by M. Clerget, and by him laid before the Academy of Sciences at Paris. It is an interesting paper to our farmers at the present time: "*Academy of Sciences, Paris—sitting of October.*—A letter was read from M. Clerget, giving an account of his discovery of the mode of making potato flour, of such a quality as to be in every respect fit for panification. M. Clerget's letter was accompanied with several samples of his productions, in the different stages of the process. Amongst them are two specimens of the flour, of nearly a yellow color, which represent, we are told, the potato in its natural state; divested, however, of the essential oil, and useful for various purposes of domestic economy, although not so fit for panification as the flour obtained in a more advanced stage of the process. There are three samples of pure white flour—one in powder, the other two granulated; in which state the flour will keep good for several years, if kept in a dry place. M. Clerget says that when this flour is mixed with that from wheat, in the proportion of cent. per cent., and made into bread in the ordinary way, it is exceedingly wholesome and nutritious, and cannot by the taste be distinguished from pure wheaten bread. This we can believe, for we have eaten bread made in the same proportions of wheaten flour and potatoes boiled and reduced

to a pulp, and found it even more agreeable than that made from the flour exclusively. Bread thus made, however, is not agreeable when it has been kept two or three days; whereas, according to M. Clerget's statement, that which is made from an admixture of his flour with that of wheat, in equal proportions, is much better, when stale, than pure wheaten bread. He estimates the saving, by means of this mixture, at from forty to fifty per cent.; but this appears to us to be an error, for the potato flour cannot be sold to to the public, with a reasonable profit to the manufacturer, at less than *two sous* per pound. Taking wheaten flour at *four sous*, two pounds of bread made of the mixed flour would cost *six sous* instead of *eight sous*, which certainly does not give a saving of forty to fifty per cent., although it does effect a very important saving. We need not observe that the mixed bread contains less gluten than that of wheat only, but we are by no means sure that an excess of gluten is favorable to nutrition. M. Clerget is of opinion, however, that if gluten be added, which is practicable in various ways, very good bread may be made with two-thirds potato and one-third flour of wheat; and in this case the saving would be enormous. He informs us, also, that if the potato flour made by his process be mixed with the flour of rye, which by itself is difficult of panification and digestion, a very nutritious and agreeable bread is made. This is a valuable part of his discovery; for in France nearly two-thirds of the rural population are compelled to exist on rye bread, as being so much cheaper than that of wheat. By the admixture of potato flour, there would be a saving of outlay, and a gain in nutrition. It was stated at the academy that a company had been formed in Paris for the manufacture of the potato flour by M. Clerget's process, and that the same progress towards carrying it out on a large scale had been made in London."

Professor Johnston, in his letters on Scottish agriculture, contained in the October number of the Quarterly Journal of the Highland and Agricultural Society of Scotland, has some interesting and valuable remarks on the same subject, which, sustained by such authority, deserve careful perusal and serious reflection. He says: "Into this manufacture great improvements have recently been introduced, and the farina is converted into British *tapioca*, into sirup, and other articles which will find a more or less ready market. The waste fibre of the potato, which was formerly considered only fit for manure, is now converted into a wholesome nourishment for cattle; and even the washings of the starch, where skill and economy preside over the process, are collected and employed as a manure. You recollect the fact mentioned to us by Mr. Binning Home, that these washings, when allowed to run into the potato drills, had given, near Stirling, a larger crop of potatoes than was yielded by other parts of the same field to which guano and farm-yard manure had been applied.

"There is little reason to doubt that new uses and new outlets for the potato will, by-and-by, become generally known. The farina, in the form of *tapioca*, is gradually finding a more extended use, and in numerous other forms it is insinuating itself into our daily diet. In Germany, a method has lately been introduced of making flour from potatoes, which has not, I believe, been tried in this country, but which is recommended as giving a better, a more palatable, and a more abundant article of nourishment than the common process of preparing potato starch. This method consists in washing the potatoes, cutting them into slices as we do turnips, steeping these slices for twenty-four hours in water containing one per cent. of sul-

phuric acid, (oil of vitriol,) drawing off the acid water, washing them several times with pure water, drying them in a stove, and then grinding them in a common corn mill. The flour thus obtained is pure white, and the siftings or bran seldom exceed 5 per cent. of the weight of the dried potatoes. The sulphuric acid, in this process, extracts the coloring matter of the potato, with certain other substances, which would give the flour an unpleasant taste. This flour will not make good bread if used alone; it requires to be mixed with one-half or one-third of wheaten flour." Speaking on the subject of starch, after quoting some experiments made to ascertain the relative proportions of starch and water contained in 100 lbs. of different varieties of potatoes, he adds, that "on the whole, the red potatoes seem to be the best starch givers."

In one of the French journals, (*Moniteur Industreil,*) it is stated that 50,000,000 kilogrammes (equal to above 112,000,000 pounds) of potato starch are annually used in France for the manufacture of potato sugar.

The following results are said to have been reported to the Cork Agricultural Society, as the amount of farina or dry flour, fit for use, extracted from 20 lbs. of sound potatoes, or in various states of decay, viz:

Sound white potatoes - - -	3 lbs.	9 oz.	0 drachms.
Unsound and diseased part cut off - -	3	1	0
Unsound minions - - - -	3	1	0
Unsound and paired - - - -	3	0	0
Unsound, none cut off - - -	3	6	0

"Diseased potatoes, useless, quite soft, and rotten, will make as good starch as the soundest, and need not have the bad parts cut off, but should be washed to prevent the earthy particles from mixing with the flour."

In appendix No. 4 we have placed an analysis of above 60 different kinds of potatoes, which is taken from Dingler's Polytechnic Journal. Although the account relates to varieties found in Germany, still it may be useful as furnishing a comparison for analyses made of those elsewhere.

In the *Echo Monde du Savant* for 1842, we find the following recipe recommended as a good one for recovering watery potatoes. It has at least the merit of simplicity: "When boiled and watery, let them lie eight days before being used, near an oven."

Potatoes are used in most parts of the country, in connexion with other fruits of the earth, as food for stock of various kinds. Professor Johnston, in the letters already quoted from the Edinburgh Quarterly Journal, speaks of a process of preparing them for this purpose recently discovered in Denmark. He says: "As I have said so much on the subject of potatoes, I may as well describe to you a method which has lately been recommended in Denmark and Norway for making the potato more available and profitable in feeding cattle than it has ever hitherto been. You are probably aware that potato starch can very readily be converted into grape sugar, and that the sirup obtained from it is largely employed in the manufacture of brandy in the north of Europe, and even of the best brandy which comes from France. In the more northern of the French wine-growing provinces, it is also mixed with the less sweet varieties of grape juice, so as to give an additional strength and richness to the wine. One of the methods by which the potato starch is converted into grape sugar is, to mix it with one-tenth of its weight of ground malt diffused in water, and to keep the mixture for some hours at a moderate temperature. The starch dissolves, and the li-

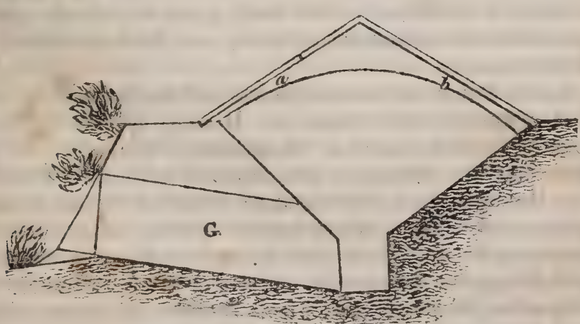
quid becomes sweet from its conversion into grape sugar. This is the method which Mr. Böggild, of Copenhagen, proposes to apply to the whole potato in order to bring it into a soluble state, to make it more easy of digestion, and thus to increase its feeding properties. He washes his potatoes well, steams them thoroughly, and then, without allowing them to cool, he cuts them in a cylinder furnished internally with revolving knives, or crushes them in a mill, and mixes them with a small quantity of water and three pounds of malt to every hundred pounds of the raw potatoes. This mixture is kept in motion and at a temperature of 140° to 180° Farenheit for from one to five hours, when the thick gruel has acquired a sweet taste, and is ready for use. Given in this state, the results of experimental trials are said to be—1st. That it is a richer and better food for milk cows than twice the quantity of potatoes in the raw state. 2d. That it is excellent for fattening cattle and sheep, and for winter food; that it goes much farther than potatoes when merely steamed, and that it may be economically mixed up with chopped hay and straw." Professor Johnston adds: "I have before me a pamphlet published at Christiana, by the Royal Society for Promoting the Improvement of Norway, in which this method is strongly recommended; also, a letter from Copenhagen, dated 29th April, 1845, in which my correspondent writes as follows: 'This invention has been more and more appreciated and applied in my native country, Norway, and in Denmark; and the great advantages with which stall-feeding may be introduced, at considerably less expense than formerly, made it suited to general promulgation.' The method has more and more gained adherents; and further comparative experiments, made by scientific and experienced persons, have proved its superiority. Thus, an experiment established the fact, that an increase of one and a half pounds of flesh is obtained from twenty-five pounds of potatoes; that the feeding of horses with this mash is found to be applicable and cheap; and all experiments confirm the fact, that potatoes used in this manner, as a food, amply afford doubly the nutritive powers compared to the food formerly used." The Professor, in conclusion, remarks: "I cannot here state my reasons for believing that there is really something worthy of attention in the alleged superior feeding qualities of the potato given in this state, but I can strongly recommend you to make experiments upon this subject. If the potato can in this way be converted into a larger quantity of beef, mutton, and pork, than has hitherto been the case, another outlet will be provided for the potato crop which may, perhaps, prove more profitable than even the manufacture of it into flour." The same observation is one, also, which is worthy of the attention of the large potato-growers of this country; though, on account of the abundance of other materials of fodder, our agriculturists will probably be little inclined to adopt any of the cheaper modes of feeding till necessity compels them, as it does in the older countries of Europe.

Another application of potato, it is stated, has recently been discovered in France, where (at Nice) a manufacturer, after six years' labor, has succeeded in producing excellent paper and pasteboard from a substance separated from the potato. The process is not given, however, in any of the foreign journals we have, nor have we seen any mention, except of the fact as having occurred.

The subject of *storing* potatoes for preserving them suitably, is one which likewise may be commended to the attention of our farmers. In Dingler's Polytechnic Journal for 1843, vol. 90, we find a description of an earth cel-

lar for this purpose, quoted from Riecke's Weekly Journal for Agricultural and Domestic Economy, No. 34, 1843. As it is highly recommended, we have subjoined a translation of the same:

"In the southeastern portions of Normandy is used for the preservation of potatoes a simple kind of earth cellar, which is certainly preferable to the usual modes, where the soil is not exposed to the pressure of the moisture. A round wedge-shaped pit, terminating in a small straight sided space, is dug in a place which has some elevation, that the moisture may the more certainly drain off. At the bottom of this pit there is a narrow entrance (G) either from the side, where the nature of the ground admits of it, or from above. The object of this is as follows: The potatoes will always be taken from the bottom, which has this useful result—that the whole heap of potatoes, which naturally sink down as often as any are withdrawn from below, remains in frequent motion. The sides of the pit must be well smoothed, and here and there burnt out with dry wood. The pit must be covered with a light roof of straw, which is so placed that it may be easily either wholly taken away when the potatoes are to be filled in, or at least some portions of it may be removed. Finally, the earth must be heaped up around the pit. Before the potatoes are brought into the pit, the surface, as is the case in other receptacles, must be laid with straw, especially on the bottom, in order to prepare the surface of the earth on the bottom and sides better. The pit is then to be filled up with potatoes, heaped up to the brim (*a b*). For protection against a greater degree of cold, some straw must also be spread out in the empty space between the roof and the potatoes. The mouth of the entrance, also, should be stopped up with bundles of straw. If there are many such earth cellars, they must not be broken up one after the other, but as nearly as possible all together. The excellent condition of potatoes in these earth cellars is celebrated. That the formation of one of them costs less labor than the labor of preparing the common earth cellar, or the usual receptacles, scarcely need be mentioned." The dimensions and shape of the one given in the Journal are as follows: G, as above mentioned, is the entrance; *a b*, the line to which the potatoes are to be heaped up, between which and the top of the roof is to be filled with straw.



A substitute for the potato is thus described in some of the public journals, the account of which is interesting, and may perhaps, at a future time, deserve more attention, and therefore we have concluded to add it to the pages of this report.

"*Substitute for the potato.*—We learn from the London Medical Times, that at a late meeting of the Academy of Sciences in Paris, it was proposed, in consideration of the disease of the potato, to introduce for cultivation in Europe a valuable South American plant, as a substitute for that wholesome esculent. The production referred to is the *Arrachia*, an umbelliferous plant indigenous in New Grenada, particularly in the most temperate parts of the continent, where the average temperature is 15° to 25° R. The Arrachia is generally three feet in height, its radical leaves twelve to fifteen inches in length, numerous, biternate, doubly incised, dentate, on long fistular peticles. The caulinar leaves are smaller than the radical, which they resemble in every other respect. The flower is a violet-colored umbel; the petals oval, accuminated and inflexed; five stamens and two style, arising from a disc of the same color as the flower. The fruit is an oblong carpel, marked with five ribs. The blooming season in October. The root is the part which is used as a fruit in the country as an article of food; it partakes of the nature of the carrot and the potato, being a kind of intermediate substance between the two. Each plant furnishes from three to four pounds of nutritious matter, one hectare yielding no less than 82,500 lbs. of wholesome food, and of course a great desideratum in the present failure of the potato crops."

It may not be inappropriate, also, at this time, to allude to the subject mentioned in the extract below. We can scarcely imagine that a vegetable of such extensive use, and so highly valued as it is, should only have been introduced into England about 350 years since. It might well deserve commemoration:

"*Festival to commemorate the introduction of the first potato.*—Festivals are frequently established to commemorate some absurd custom, but the following celebration, in honor of the potato, has something in the subject of it of real usefulness to mankind. Several of the German States, we are given to understand from the Athenæum, have instituted feasts in honor of the introduction of the potato; and the anniversary of its importation has just been held as a jubilee at Bavaria. At Menterschwaige, near Munich, a festival was observed on the occasion, in which dishes of the poor man's especial root, variously dressed, had the place of honor on the table, while the bust of Sir Francis Drake, crowned with garlands of oak, and presented to the commune for the occasion by its sculptor, Schwanthaler, occupied the centre of the room.

"In France, a monument is about to be erected to Parmentier, commemorating its introduction into that country. It may appear to our readers that the honor paid to the memory of Drake was really due to Raleigh; but it is probable that the Germans are literally correct. The first colonists sent out by Raleigh were disheartened when Drake touched at Virginia, and he consented to bring them home. Lane, the governor, who is believed to have brought with him the first tobacco, may have brought, and probably did bring, the first potato; if so, though indebted to the enterprise of Raleigh for the discovery, it was Drake's ship that actually introduced the first root."—*Bulletin of Medical Science.*

POTATO ROT.

When, in the report of last year, the potato crop was under consideration, it was hoped that if another year did not relieve us from its rav-

ages, at least so much light would be thrown on the probable cause of the evil as would enable us to remedy its destructive effects. To our regret, however, we find that such has not been the case. As a general fact, the effects have been more severely felt than before. While the public journals and agricultural papers have abounded with numerous articles embodying lamentations and suggestions as to the cause or remedy, we scarcely seem to be any nearer the desired result. It is well known, also, that a disease or blight of a most destructive character has made its appearance both in Great Britain and on the continent, which seems to be very similar to the one which prevails on this side of the Atlantic. We have derived one advantage from this circumstance which may essentially aid us in our investigations. Observations of scientific and practical men, conducted under all possible inducements to ascertain the extent and cause of the evil, and to furnish the best remedy or preventive, are thus brought to our notice, and we are enabled to compare these with such as have been called forth in our own country. As a general thing, too, the former are marked with a precision and minuteness of detail which evince a decided superiority in the mode of observation and deduction to the random conjectures of mere casual notice. There are indeed honorable exceptions in the communications made to our own journals; but there is too often a looseness of statement, and want of particularity and discrimination, which impair their value as materials on which to found any important conclusion. We know not the result of the offered premium by the Farmers' Club, and the directions drawn up by Dr. Gardner to aid the investigations of any one who might be disposed to obtain it. We believe, however, that no very satisfactory result has been reached. The amount of information on the subject, such as it is, is greater than in the previous year. The alarm then created has had its influence to turn the attention of many in all parts of the country to the first appearance, during the season, of the dreaded influence. The various views then suggested have still each its own supporters and advocates, and the statements made do not so decisively, in every respect, favor any one theory as to leave no doubt on the minds of many. We shall advert to the disease, first, as it appears in our *own country*, and to the facts which are recorded respecting its progress here during the last season; and then, also, for comparison, draw out the features of that which has occasioned so much alarm and distress in *Europe*. This method appears to us to possess some advantages, as there may be a similarity in some respect, and yet some distinctive and peculiar features belonging to either. We shall, also, for the sake of convenience, throw into two appendices the various articles and statements to which reference may be made, so that the opinions of those who may be considered exponents and advocates of any particular views may be seen in their connexion in their own language, including also such communications of our own correspondents as may be deemed best. This course may increase the size of this report, but such an arrangement possesses the advantage of placing these documents conveniently at hand for future reference and deduction, instead of its being needful to search through numerous volumes to find them. In the main, we adopt the course of arrangement for our remarks which was taken in the last report, though we shall here and there generalize or subdivide, as seems to be most expedient.

It will be unnecessary to advert to the *appearances* of the disease there

described, and minutely repeat them, and we shall therefore content ourselves with adding such other points as are new, or more clearly developed.

As there seems to be no variance of opinion as to the fact that the disease is not confined to any particular *kind* of potatoes, we do not deem it necessary to dwell on that point, except barely to say that the Rohans and long reds appear to be perhaps the most exempt. It seems to be the fact, as will be observed by reference to the articles in the appendix, that the evil in some cases has not prevailed where it did the previous year; though in many others it has done so even to a worse degree than before.

1. As to the *extent* of range embraced in its appearance. So far as we can ascertain, it appears to have been observed further east, west, north, and south, than in the previous year. It has been noticed in the British dominions, both Canada and Nova Scotia; it is mentioned as having been experienced in Illinois, Indiana, and Michigan, and as far down as the lower part of Ohio, in the southeastern part of the State. It may be, that the evil which is so characterized in some of these sections is nothing more than the common premature decay, produced by the ordinary atmospheric influences, as the accounts are not sufficiently definite to enable us to decide. Such seems to be the view taken by the editor of the Ohio Cultivator, who, after giving a statement from the Sandusky Democrat, says: "We are inclined to think that the rot which our Sandusky neighbor speaks of is not of the same kind as that which has for the past two years prevailed in some of the eastern States, and is now exciting so much alarm in most parts of Europe. * * * * Potatoes often rot both before and after being dug, from other causes than this disease; such as being killed by frost before maturity; an excess of wet, &c. And when buried in a heap, they not unfrequently become heated and spoil, by being covered too deeply before the weather becomes cold." We regret that there has not been more care, as this fact, among others, has an important bearing on the subject, and such neglect impairs the general conclusions which may be drawn.

2. *The particular period of the season* in which it has been noticed for the first time during the past year, is *earlier by a month nearly* than in any of the accounts of the year before. Thus the Worcester (Mass.) Spy, in reference to this subject, says, early in July: "The blight which caused such destruction to the potato last year has thus early commenced its ravages the present season. We have examined a field belonging to Governor Lincoln, which we are assured exhibited a perfectly healthy appearance on the *third* instant. On the *fifth*, portions of the vines showed indications of disease; and on the *seventh*, about half were more or less shrivelled—many of them shrunk to half their former dimensions, and some of the leaves already turned brown and nearly dry." Allowing this to be the same disease, this is an important fact. We are, however, left in some doubt as to this question, since the writer states that on opening one of the hills most affected, both the seed and the new set of potatoes were sound and looked well.

In the accounts given by Mr. L. Ford, also, of Cummington, and E. B., of Pompey, New York, the disease is said to have affected the vines on the 14th of July. The account of Mr. B. P. Johnson is dated July 18, and, he says, "within the last few days." Here are three independent witnesses, living remote from each other, and communicating with different agricultural papers; and in this respect their testimony has not a little bearing on the subject, provided it was the disease. But as, in their statements, with

the appearance of the vines simply, they do not connect the appearances exhibited with the tuber, except as to the probable result which they conjecture might have taken place. The appearances, and not the supposed causes they present, are the subjects with which we are concerned in this part of our examination, and hence we have not thought proper to refer to this point, except so far as it may enable us to determine the commencement of the cause, or at least its observed development. These are the earliest notices we have been able to find mentioned in the papers. From this time on through the month of July, we find complaints of the begun evil.

3. It is a question of some importance to determine the precise *point* where *the attack commences.* As the disease was not in general anticipated or dreaded in 1844, the earliest appearances were but little noticed, and the attention was mainly directed to the condition of the tubers and the partial or utter decay which they experienced. Little, comparatively, is mentioned during the past season as to the form of the evil on the root itself, but rather to the appearance exhibited *above ground.* There is great uniformity of opinion in this respect even among the advocates of different theories. Almost all agree in a certain condition of the vines as a precursor of the more fully developed rot in the tuber. Yet, at times, while looking at the accounts before us, we can scarcely avoid feeling that there may be a combination of two or more great causes to produce the effect. In very many cases there seems to be no effort to trace the influences any further than their earliest stage. By almost unanimous consent there are more stages than one. How far these may be modified by extraneous causes may properly be a subject of future examination. The *earliest* visible stage which attracts notice, allowing that one disease or evil is not mistaken for another, in whole or part, is in the *leaves,* and, it would seem, in those which are *extreme.* It does not, indeed, follow that here is the original seat of the disease. Such an appearance might take place merely as a first development, where its source might be found in the stem, or, in some cases, in the root. It is well, however, to note with the minutest accuracy, so far as we are able, the particulars which fall under the naked eye, or are discoverable only by the power of the microscope, and then the task is to be undertaken of discriminating between what may be *essential* or only *accidental.* We believe that, by a careful examination of the descriptions, something may be done, by strict adherence to this principle, towards removing errors. A *wilting*, *curling*, and *drying up of the tops of the leaves and vines,* is one of the most common and first appearances observed. On examination, it is discovered that the *stem* bears marks of an attack previous to that on the foliage. A brownish or dry spot is seen sometimes only small, then extending some inches on the vine. The place where this appearance has been observed is a *little above where the vine enters the ground.*

A writer in the Indiana Farmer and Gardener, over the initials "J. T. P.," and supposed to be Mr. Plummer, of that State, speaking of some observations made by himself, says: "The disease, in every instance, was found to be confined to the vines. These were generally affected near their entrance into the earth, a few inches above and a few inches below this point. A person, in a general review of the field, would perceive nothing but a luxuriant crop of potatoes; on passing watchfully along the rows, he would discover here and there some prostrated vines, with wilted leaves. On close examination, he would find at the points named a perfectly dry

decay of the stem; the pith entirely gone; the cuticle also removed or dried to imperceptible thinness, and nothing is left but the ligneous fibres, whitened by disease, and sometimes separated laterally. This is the worst stage of the disease yet observed. The parts below this point are perfectly sound at present. On turning to other stems, indiscriminately, whose leaves and vines are apparently in the full vigor of health, we perceive the earliest encroachments of visible disease. Here we see a little discolored patch of cuticle, dried up and sunken to the ligneous fibres below, the parenchymatous matter among the cuticular tissue having disappeared." On scraping away this dead cuticle, he states that the ligneous texture is still found to be living; " but in the next plant that is also decayed; and in still another, we witness the destruction of half the pith; and in another the pith is all gone; and then we arrive at the last stage, or total rottenness. In most instances, there are several such patches of cuticular decay, of irregular figures, but there is a well defined line of separation between the dead and living parts. On slicing, lengthwise, one of the vines in which these spots of decay have penetrated into or through the pith," he adds, " portions are found of solid, and apparently sound pith, in the intervening portions of the stem." "In several instances, also," he says further, " the returning sap being interrupted in its descent by the cuticular decay, formed small tubers (perfect potatoes) just above the diseased point." " There is no apparent erosion of the cuticle, but the idea is suggested of all the pulpy matter in it being abstracted, and the cuticular film collapsing upon the parts beneath." " We may safely say, upon these observations, that the disease undoubtedly commences on the *exterior* of the vines, and that the upward circulation is continued long after the downward current is partially or wholly intercepted; that the disease tends to penetrate into, and not to pass along the vines; the tops perishing only when no nourishment can be obtained from below."

We have quoted the above description, not only on account of its being evidently that of a careful observer, but as giving the most minute account we have found this year of the gradual development and progress of the disease. That the vines bear some important relation to the early stages of the disease, would also appear from the statement of W. Bacon, of Mount Osceola, who speaks of the evil as " first showing itself in a very small blotch on the side of the stalk, which continued to spread until it had gone round and through the stalk, when the last, at the particular point of the disease, became dry and hard, as though it had reached its maturity. The death of the top soon follows, but the lower part remains green for awhile." He also found that in this stage of the disease, " mowing the tops prevented the evil from being developed in the tubers." Mr. Pearce, of Hamburg, also said to be an excellent and observing farmer, " saw that his potato vines were affected, and pulled several hills to examine the roots. They were sound, and left separated from the stems or tops." " The potatoes in all the adjoining hills were rotten at the time of harvest." The Hon. J. Crary, of Salem, N. Y., in the Cultivator for April last, speaking of the appearance of the disease in 1844, says: " The first symptom of failure is in the stalks of the potato; they become dry, and the leaves turn black; the growth then ceases, and the potato becomes rotten before it is ripe. The fibres that connect the stalk with the potato quit their hold; and when you grasp the stalk and pull, with a view to raise the potatoes out of the hill, the roots break and leave the potatoes, or rather slip out of the hill without raising the po-

tatoes." "M.," likewise, of the Indiana Farmer, says: "I discovered that the leaves of the tops (of one patch) of my potatoes, which extended horizontally, were dead. They had the appearance of having been frost bitten, and were of a dark brown color. I took no further notice of it until two days after, when I found the entire tops were in the same fix, though they had always kept their erect position." The notice respecting the first development of the disease in the field of Governor Lincoln, in Worcester, already given, will also be recollected as speaking of the vines and leaves as diseased, but the seed and sets sound. "Philo," of Portland, likewise speaks of the first visible effect being noticed in a blight on the tops.

But there is yet another stage, it would seem, in which the vines are not necessary. The experiment of E. G. Buxton shows this. He planted in the spring a few potatoes in some dry tan-bark in a dark, dry place in his cellar. On examining them in October, he found a number of new potatoes of the size of a hen's egg down to a mite, which exhibited the same appearances of rot and disease as did other diseased potatoes. The same fact is also stated to have been observed in Germany by Von Martius, in 1842. (See his essay, translated and appended, among other foreign papers, to this report, in appendix No. 6.)

It is important for us to know the earliest indications of the disease before it is so diffused that it cannot be arrested. Means may then be more readily devised to check it in its incipient appearance, and thus this valuable crop be saved from the destructive ravages it now seems doomed to undergo. Would our farmers generally follow the example of Mr. Plummer in this respect, much more information could be gleaned as to this point.

4. As to the stage of the disease in which the *tubers* exhibit marks of its influence, the appearances do not vary much from what was observed the previous year. Mr. J. M. Weeks, of Salisbury, Vermont, speaks of it as in the form of a blister upon the skin; and it soon makes progress towards the heart or middle of the potato, forming, as the disease advances, a kind of fungus upon the surface of the tuber." In other cases, he says: "It is not uncommon to trace the disease directly down from the stalk in black streaks to the middle of the tuber." Mr. Freeman, also, of York, Maine, says: "The first appearances of the rot are dirty yellowish spots, similar in appearance to iron rust; it penetrates the potato, and, in a short time, turns to a dark color, and the work of destruction is finished. They appear to smell and taste similar to a frost bitten potato." The editor of the Monthly Visiter, after quoting from the Massachusetts Ploughman a communication of the Hon. Merrill Allen to the Old Colony Memorial, says: "In the fall of 1844, a few days before they were dug, the growth of the potatoes was arrested by the sudden dying of the tops, which seemed to be stricken as with the blight which frequently takes place at an earlier season. The vines being thus killed, we dug them perhaps a fortnight earlier than we might otherwise have done; and it was observed, when they were disposed of in their bed, that the skin peeled off easily." Mr. B. P. Johnson, of Rome, after first noticing the appearance of the tops, says: "In some instances, where the potatoes have been dug, on cutting them open a small black spot is found in the centre. In others, the potato appears sound and healthy." "N. N. D.," in the Cultivator of February, also, speaking of the crop of the previous year, says: "The rotten potatoes were full of long white worms," and "the odor was intolerably fetid. This, of course, was at the most advanced period of the development of disease."

Another fact observed is, that the tubers, when dug and stored away apparently sound, even when the crop while growing exhibited a generally healthy appearance, have rotted. The case has been mentioned in the public journals of a gentleman in the interior of Massachusetts, who sent several hundred bushels of potatoes to Boston apparently sound and good, but which, soon after their arrival, he was requested to call and take away, as they were decaying and most offensive; and out of 600 bushels he obtained 100 bushels of sound potatoes. There seems to be no reason to doubt that the tubers may be found in very different states even in the same field, and sometimes also in the same hill, exhibiting a progress which, if more carefully observed, might aid in more accurately fixing upon the point where they might be used, or otherwise.

4. *As to the kinds of soil, locality, modes of culture, &c.*, there is still a diversity in the accounts furnished. These vary according to the various theories adopted by various individuals to account for the evil. To advert to some of the statements.

(*a*) *Soil, locality, &c.*—Both old ground and new ground were tried by Mr. Colt, of Paterson, New Jersey, and the *new* ground gave the best yield. The editor of the Monthly Visiter says that, in the high grounds, in 1844, where the latest broken up pasture grounds have usually produced the best potatoes, the greater portion of the crop was lost—more so than in other grounds. Mr. A. Robinson recommends light ground, which, he says, is so porous as not to retain the abundance of wet, &c. Mr. Rhoades says, respecting a crop in 1844: "One field was new land, very high and dry; the other was older land, and moister. Every potato grown in the first field was sound; but in the other, some were diseased. The next season (1845) one of the lower fields was again planted, using seed from the high ground. The summer was drier than in 1844, and the produce was all sound, as was that also on the adjacent green sward, planted with the same seed. On part of the green sward, planted with infected seed, more than half the crop was lost." He concludes that low moist localities are most obnoxious to its influence. Mr. Lane mentions that where land descended towards the north, he found his crop much better than in other exposures. Mr. Hammond, of Conesville, says, with reference to the crop of 1844, that "on dry cool lands, not rich in putrescent manures, the crop escaped." It was observed by different persons in the New York Farmers' Club that potatoes from a copper region, and also from an iron one, did well. It would be interesting to ascertain the geological condition of those particular regions where the disease has been the worst.

(*b*) *Culture, &c.*—The use of sound tubers seems to be not always considered indispensable. Mr. Thompson, of Astoria, stated in the New York Farmers' Club that he cut off the sound part from *diseased* potatoes of last year, and planted them with perfect success. So Mr. Townsend, of Astoria, also planted from the diseased crop, and had potatoes. In most cases, however, it is stated that the seed was sound, though this did not always secure from disease. Potatoes planted in manures that are rich and highly putrescent appear to be most liable to the influence of the rot. Mr. Weeks, of Vermont, says: "My own observations, corroborated by the testimony of hundreds of others, show, very clearly, that when the land is manured with that kind of manure which is highly charged with ammonia, the malady is most fatal. Where the same land was planted side by side, if manured with manure so rotted as to have lost its smell, very little disease is

found. Manure in a state of fermentation, when applied to the potato hill, or manure that will ferment, will be apt to engender disease." He adds: "We suffered greatly by the malady last year; this year we have taken a different course in the preparation of our potato lands. Instead of using any manure, we selected land that was highly dunged last year from the sheep pens and cattle stables, and was in corn. We ploughed twice, as usual, and planted early in May, three feet apart both ways; we cut the potatoes, and used as much lime as would stick without water. As soon as the plants were out of the ground sufficiently to live, we made a compost of salt, leached ashes, lime, and plaster; incorporated the whole together, and top-dressed every hill with a table-spoonful of the compost, and covered it in the hill at hoeing; hoed twice; then in July sowed salt broadcast, two bushels to the acre. The potatoes were good." "Philo," of Portland, says: "Potatoes rot most where they come in contact most with manure. Manure coming in immediate contact with the growing crop, by being put in the hill or spread upon the ground, forces its growth, especially of the tops, too fast." "I am apprehensive that manuring on the top of the ground, and in the hill, induces too much growth in the early part of the season." "I am inclined to think that potatoes would do better, all things considered, without any manure in the land. But should manure be applied, let it be ploughed in to the depth of 15 or 16 inches, if possible." He also suggests drilling as useful. Mr. Sanderson, of Chesterfield, New Hampshire, states that he planted his seed as soon as the ground would admit of it, and manured them in the hill with well-rotted manure; planted the largest, and was careful to get none that were not sound; kept the ground free of weeds till autumn, and dug them in the middle of October: they were good; while his neighbors complain that their potatoes were rotten. Mr. Robinson, after stating that nowhere had he found any rot on light soils, while on moist soils highly manured it appears to have had great effect, adds: "This year I was so wary as to plant all light ground—some sward and some old ground—all planted early; all manured lightly in the hill with compost manure, made from rich low ground, hauled into the yard after haying to mix with cattle manure, and hauled out in the fall. This kind of manure will not ferment. My crop this year is tolerably good, and all sound. It is found that the early planted better escape the rot than the late." Mr. Freeman, of York, Maine, says: "But few if any escaped, except the *early* planted, and not even these when planted on unfermented manure." Mr. McGuffy, of Ohio, states that he planted 2 patches of potatoes of about one sixth to one-fourth of an acre each. "One of them was on land on which cattle had been fed or fattened with corn the fall previous, by which means it was highly manured. On this land one bushel of seed was planted, of the Meshannock variety, cut into small pieces, and 3 or 4 pieces dropped into a hill, the hills 4 feet apart, and the ground well cultivated in summer." "The tops grew with great vigor, covering the whole ground, and, owing to the fine rains in autumn, they continued to grow until destroyed by the frost in autumn. The crop was large, and the potatoes of a very fine quality." "The other piece of land was planted with 3 pecks of the same kind of seed; but *no manure* had been applied, and less labor was bestowed in cultivation. The weeds were allowed to grow after wheat harvest, and the tops, which were much less luxuriant than the tops of the other piece, were all ripe and dead before the frosts came. The yield was less by one-half than in the other case." "Both of these lots of potatoes were dug at

the same time, and buried in the same manner, in trenches in the ground. In a few weeks it was discovered that those from the rich ground, and which had their tops destroyed by the frost, were beginning to rot. The disease spread to such an extent that it was doubtful if any of them would be saved. But those from the ground which had no manure, and where the tops ripened before the frost came, have not shown any symptoms of decay." In two neighboring fields, in one of which the potatoes were ripe before the frosts appeared, there were no signs of rot; while in another, in which they were green until the frost killed them, they had nearly all rotted. The Hon. Mr. Crary states that those which were covered deep were as good as usual, and those with a shallow covering were useless. In a case stated by Mr. Hammond, of Conesville, some potatoes were planted where potatoes had been buried the year before, and the straw used about them turned over for manure; they were more rotted than anywhere else. Some persons made use of lime, and the potatoes rotted; others used lime, and had good potatoes. New varieties as well as old were affected; and in the case of Mr. Dox, a variety from the ball also were affected by the disease. Potatoes whole and cut seem equally to have felt the effect of the evil.

The letter of Mr. Chase, of Calais, Maine, contains some interesting particulars, which deserve notice under this branch of the subject. It will be found with the other letters and statements already referred to in the appendix No. 5. He says: "Some of my seed-potatoes I cut, and put lime with them in the hill at planting; some I planted whole, with lime; some cut and some whole ones without lime. Some seed I procured from a distance, and which was grown on an entirely different soil. In some of my compost manure I made use of a large quantity of potash. In all these cases the disease upon the potato was apparently the same; nor did the quantity or quality of the yield vary. The greatest difference was found in potatoes planted in different soils. On that soil which was stimulated most by manure, and especially by manure in the hill, the rot was the greatest. On dry loamy soil, the disease did not affect the potato so much. On wet land, and especially on wet clay land, the disease was the most fatal. It was observed that where lumps of clay lay so near the new grown potato as to touch it, the potato would be rotten on that side touched by the clay. The potatoes which grew nearest the surface and nearest the stalk were also observed to be most rotten. Those soils on which the salt rock-weed was used as a manure in great abundance, and where the influence of the salt water fogs was felt, were equally if not worse affected by the disease." The statements in the preceding letter are important, on account of their bearing on the different suppositions which have been adopted respecting the nature of the disease and its desired remedy. Mr. Slingerland, of Bethlehem, New York, in a letter communicated to us, speaks thus of an experiment the past season. After mentioning that, in 1843, he sent to Long Island for a particular kind of seed, and that they rotted worse than any he had before employed, he says: "Last year, 1845, I planted four acres more of the same kind of seed, and in the last of May I planted six acres more in the same kind of soil—a sandy loam; the four acres planted early did not yield as much to the acre as the six acres I planted late, but the early planted were all good, with few exceptions; the late planted, one-half of them rotted as soon as they were dug, and the other half were not fit for market. I had to feed them out to the cattle. I then made inquiry of my

neighbors about their potatoes, and they told me that the early planted were good and did not rot. The superintendent of the poor-house of this county planted thirty-five acres. He planted them all early, and he told me that they were all good. The late planted potatoes were full of water when the frost came and killed the vines, and this caused them to rot; the early planted, when the frost came, were ripe, and no sap in the vine or in the potato. We dug the early planted in the morning, and let them lay in the sun till night, and dry, then picked them up and put them in a dry place, and they kept good." One farmer was mentioned in the New York Farmers' Club who is said to have pulled up twenty hills before they were fully ripe, and scraped away again the earth around the hills; the whole field rotted save the twenty hills.

5. *The influence of the season*, so far [illegible] as observed, deserves notice also in a collection of facts [illegible] respecting the operation and progress of this evil. It is not necessary [illegible] in this place to bring into consideration any particular theory as regards the relation the facts have to its proximate or immediate cause. Our object is to record whatever may have been deemed of sufficient importance to attract the notice. In general, we know that the season was very dry and hot during the month in which the growth of this plant usually takes place. Mr. Freeman, of York, Maine, under date of September 25, 1845, alluding to this subject of the weather, says: "Last year the rot seized the potatoes about the last of August. It will be remembered that in this section of the State we had very warm weather, with frequent rains, about that time, and it invariably cleared off very warm; when, formerly, it generally came off cooler immediately after rains. This season has been the warmest for many years. The rains in this section commenced one month earlier than last year—say the last of July and first of August; consequently, the most of potatoes, excepting those planted very early, and of an early kind, were young and tender when these rains commenced. The soil being heated by many days and *nights* of sultry weather, actually scalded the potatoes, and but few, if any, escaped, excepting early planted, and not even these when planted on unfermented manure. It will be remembered that, though we had frequent rains, they were not heavy ones; barely enough to wet the manure in the hill, which doubtless caused them to rot more rapidly than if the rains had wet down deeper. It will also be remembered that the sun came out very hot after these rains, killing the vines of the potato, whilst the heat and wet under the surface were doing their work of destruction to the young and tender tuber."

Mr. A. Robinson says: "The past season has been one of great extremes of heat, dryness, and moisture. I speak particularly of our vicinity, where the earth was so severely parched, wet, and dry, that we had nearly given up hopes of a crop. After a very heavy rain, it remained hot, while we had alternate extremes of heat and rain, which set the earth in great fermentation—a state very injurious to some sorts of vegetation."

The editor of the Massachusetts Ploughman, commenting on Mr. Ford's communication, speaks also of the hot weather, and says: "It is certain that we have not had a warmer season for a long time."

Mr. B. F. Wilbur, of Buttervale, August 30, says: "The season here, from the middle of July up to the present time, has been uncommonly warm and wet; whether this blight will be followed with disease in the root similar to that of late years, is a matter as yet alike undeterminable. Time, however, will soon tell. It is to be feared that the rot will follow. Potatoes in

this vicinity, up to within about 10 days or a fortnight, have looked very promising of a heavy crop."

6. *The gathering and storing the potatoes*, with the circumstances which were observed at that period, are also worthy of some notice, so far as any thing peculiar is stated. We may, under this branch of the subject, again refer to the letter of G. F. Chase, of Calais, Maine. He says: "One experiment I made, the result of which I think important. As the potatoes were dug, a part of them were put into barns, and a part put in heaps of 50 bushels each on a dry part of the field, and covered first with straw, and then with dirt four or six inches deep. I left them here as long as it was safe on account of the frost. We found, on taking those from the barns to the cellar late in the fall, many of them had rotted, and others looked sickly. But those we took from the heaps in the field to the cellar, being the latest removed, were as bright and sound as when dug, except a few which had entirely rotted, and which we supposed had commenced rotting before they were put into the heap."

Mr. Wilbur says: "We would caution farmers not to be in too much haste to harvest their potatoes; the tops may be dead; the bottoms, by remaining the usual time in the ground, will be likely to improve. Besides, I am inclined to the opinion that by letting the potato remain in the ground till the proper time to dig, may tend to make it keep better after it is dug." The editor of the agricultural paper which contains this letter approves of the practice of letting the potatoes remain in the ground till they are fully ripe. Mr. Bacon, of Mount Osceola, says: "In one case, a farmer dug a very few hills when the vines first showed symptoms of disease, and carefully buried them and let them remain until the usual time of digging, when they were taken out all sound, while most of his crop had suffered essentially. There can be no doubt that when potatoes are dug so early as the rot came last year, they must be put in small bodies—kept cool and excluded from the atmosphere. Their tendency to heat, and thus become heavy and insipid, warrants us in this conclusion; and so we infer that the letting them remain in hills with the tops taken off until the usual time of digging is a much cheaper and better way than to dig and put in cellars, or on floors in piles. Another course of proceeding which has come under our observation was adopted by some Irishmen, who had known this enemy to their favorite esculent in 'the old country.' When they saw the crop smitten, they dug it immediately, and piled the potatoes on the surface of the ground, taking care to guard them from sunshine till the job was completed, when they covered the pile entirely with clay. The result was probably as they had known it to be aforetime—their crop and the potatoes of good quality. The clay undoubtedly acted as a twofold agent; kept them cool, and excluded the atmosphere and storms."

The editor of the Monthly Visiter, speaking of the crop of 1844, says: "The top of the bed was kept open, as far as it could be safely done, until the approach of severe frost. We are inclined to think that the potatoes perished, in consequence of being taken out of the air, perhaps a fortnight too soon." "Our belief is that the effects of the disease, which appeared on the killing of the vines, might have been avoided by keeping the potatoes in the ground until they had been perfectly ripened." Another person says that part of his crop "were carried directly into the cellar and put in a barrel; the remainder were put upon a wood-house floor, where they remained two or three days, till they were well dried; after which they were

put in the cellar. Those which were first put into the cellar in a barrel decayed entirely, while the others remained sound, and were good potatoes for cooking."

7. As to the point whether the disease is *contagious* or *epidemic*, we have met with but litte additional information. Instances are mentioned of potatoes in the same hill being partly sound and partly diseased; but this would not absolutely prove anything, as, even in the case of contagious diseases, (admittedly so,) it is not a necessary result that every person who is brought into contact with the person diseased becomes affected. In general it happens, but not always. And so, even were the disease of the potato contagious, they might equally and independently be affected with the same general malady, but not of necessity borrowed of each other. The question whether or not it is *epidemic* will be decided by different individuals, very much according to the theories which are adopted respecting the origin or source. There are facts stated which are alleged to be both for and against the supposition.

8. The views entertained respecting the *origin* of the evil are numerous, but may be included under three or four general divisions. Some new suggestions have been added to those before advanced. It is believed, however, that in many cases *accidental* circumstances have been mistaken for *essential* particulars. Whatever cause may be supposed, there will necessarily be some modification of its appearances, produced by various extraneous influences; so that it is proper, as far as possible, to confine ourselves to what may be viewed as truly essential in ascertaining the nature of the influence by which the great evil has been caused.

(*a*) The *insect* theory has still its advocates. The existence of a worm is stated in the Northampton Courier, as observed by Dr. Stebbins, but the statement is too indefinite to fix it as the origin of the particular evil now under consideration. So, the editor of the Pittsfield paper speaks of "a potato vine to which was attached insects, and, on cutting the stalk, a bug about one inch long was found in the centre of the same;" but this obviously could not have been the general cause of the disease, for no such appearances are generally mentioned. Dr. Lee, the editor of the Genesee Farmer, likewise, it is stated in a public journal, has made examination of the potato crop throughout central New York, and finds in all the cases that the "curling and blight of the vines is attended by an insect. The parent is probably the beetle. It punctures the vines just above the ground, and deposites the egg in the pith of the stalk where it hatches. The larvæ eat off all the stalk but the outer bark, when the vine withers and dies." It is also added: "Dr. Lee thinks that this prevents the ripening of the tubers, and disposes them to decay." We have not seen the statement of Dr. Lee himself, if it has been published in detail. It will be observed, however, that the description respecting the appearance of the stalk corresponds very accurately with that mentioned, and which we have already quoted, by "J. T. P.," (quere? Plummer,) in the Indiana Farmer, &c.; also those of W. Bacon and "E. B."

Another view respecting the operation of insects in causing the evil, is that which attributes it to the attack of a little *bug*. Thus Mr. Ford says: "This morning I examined some of my potatoes, and found some of the leaves of the top and stems dead, and many of them wilted; and among them a little bug about the size of the cucumber bug, with a sharp beak, with which he was piercing the stem. On further examination, I found

them on almost every hill; they were very active, and, by dodging or flying, would elude my grasp. Whenever they punctured the stem, it would seem to wither almost as soon as if broken off. Now my opinion is, that these bugs, by puncturing the stem, drawing off the sap and perhaps poisoning it, are the cause of the disease; and the tops being thus affected before the potatoes are ripe, causes the root to rot. On referring to Doctor Harris's report on the insects of Massachusetts, I find this kind of bug is the *phytocoris lineolaris*, of the order called Hemiptera, and is described on the 161st page." The editor of the Massachusetts Ploughman, to whom the letter of Mr. Ford was addressed, in July, 1845, says: "We think it probable that insects contributed to the disease of the potato last year and the year before. The hot weather, also, contributed to increase the mischief and to encourage these insects. There may have been several causes conspiring to produce the effect that was witnessed last September. It is certain we have not had a warmer one for a long time. Dr. Harris noticed this insect on the potato in 1838, when much mischief was done by it. We think it more philosophical to suppose that grubs or insects are the cause of the blight in potatoes, than to suppose disease in the plant."

Respecting the insect above mentioned, Dr. Harris observes: "It is most abundant during the months of June and July. It seems to be very generally diffused throughout the Union. The history of this species is yet imperfect. We know not where or when the eggs are laid; the young have not been observed, and the insects, during the early period of their existence, have escaped notice, and are only known to us after they have completed their final transformations."

The insect theory, in another form, is advocated by B. F. Wilbur. We have three communications made by him to the Massachusetts Ploughman; one of August 26, another August 30, and yet another in October, 1845. In the first he says: "I have examined one or two pieces affected, and find the *blight* (if so it may be called) caused by an insect of the species *aphis*, or *plant louse;* and so rapid is the ravage in some fields, that the tops bear somewhat the appearance of having been touched by the frost. Probably wherever the insect attacks, the tops will prematurely die." Again, August 30, he says: "Naturalists have described numerous parasitical insects, but among them all I do not find a single description in the books which exactly answers to the *aphis* of the potato—for so I shall term it. It is, however, so like the aphis of other plants, that it cannot be mistaken as to its class. I have never seen anything of the kind on potatoes before; others perhaps have." He thus describes it: "It is of a transparent green color, varying in size from that of a tobacco seed to that of a duck shot, and the largest size have wings. They are generally found on the underside of the leaf; wherever they feed the blight shows itself, and the probability is that they extract the vegetable juice or sap, the loss of which to the plant causes the mischief. If only the stem be attacked, the whole leaf withers and dies. I remember when the blight struck my potato crop in 1838, the tops looked at that time very much as now. The bottoms, also, then were affected. But at that time I did not think to look and see whether any insects preyed upon them as now. I think it most likely, however, that they did. Last year I did not notice much that appeared like blight in my potato field, though the bottoms in spots were somewhat affected with the rot at harvest time. Whether this *blight* will be followed with disease in the root simi-

lar to that of the last year, is a matter as yet undeterminable. It is to be feared that the rot will follow.

Again, in October, Mr. Wilbur writes that he had been visiting some of the best farming towns in Piscataquis county, in Maine, and says: "I was at the trouble of examining several fields, and in every instance found the *aphis* preying more or less on the tops. The rot, as apprehension was expressed in a former communication, has set in." "I shall not attempt to theorize on the subject of this potato disease—for so, I suppose, every body is agreed to call it—though I am strongly of the opinion that *lice* on the tops is the sole cause of it. It is very natural to suppose that a premature decay of the tops will have a corresponding effect upon the bottoms."

A writer who signs himself E. B., at Pompey, New York, also mentions, in a letter to the New York Tribune, quoted in the American Farmer, the appearance of insects, to which he attributes the cause of the potato disease. After stating that he had just observed a few tops of his potatoes beginning to wither and curl up, he says that he examined the withered tops and soon found a green fly, about one-fourth of an inch in length, upon every top that had begun to wither, and on most of them two; some had four, and a few six. "On one top I found four young flies, about half the size of the adult, and on three others one each, about one-fourth grown. This insect, I thought, must be the cause of the disease; commonly called the curl-top or potato rot, since I found it on every diseased top in 30 or 40 cases; and, usually, on that part of the plant which had begun to wither, near the healthy part of the stem. On the stem of one where there was a small globule of viscid transparent liquid the stem had begun to droop, but only so that it could scarcely be observed. Another globule, on the upper side of a curled leaf, on which a fly was sitting, was found to be sweet. Many of the leaves that were much wilted felt as if a glutinous liquid had been spread upon the upper surface." "In almost every case two flies were found on the same plant, differing a little in size and color; the lesser being of a darker green, and the larger containing many eggs, which it appeared to be depositing. Only one egg was found in the stem of the plant, yet there were many places apparently stung upon the diseased stem, and the effect of this reached down, in some cases, three or four inches into the heart of the stem." "From the above observations, these conclusions appear to be evident: that the sting of this fly causes the curl-top; that it breeds upon the stem, and the numerous progeny live upon the plant, sucking up its juices and its vitality."

The editor of the American Farmer remarks: "We readily conclude that the green fly found on the potato vines, as above described, would affect the quality of the potatoes, preventing them from arriving at maturity, and if left for any considerable length of time in the ground after the tops had begun to decay, would produce a second growth, by which the tubers would be rendered useless for cooking; but we doubt whether the fly here spoken of is the *cause* of the *general* rot, which has been so prevalent of late years."

The insect above mentioned seems to correspond well, in most respects, with the genus *aphis*, described by Dr. Harris, one species of which is said to be the probable cause of the blight in the peach tree. He speaks of their ejecting "a honeyed fluid," the result of their sucking up the sap of the plant which they attack. Dr. Camp and Mr. Patillo, both in the Cultivator, and Milton Burril, of Stockbridge, mentioned in the Bennington

Gazette, also express their opinion in favor of the idea that insects are concerned in producing the disease. Whether or not these insects may be viewed as *the* cause of *the disease*, it must be allowed that they are the cause, probably, of *some of the effects* observed. One of our correspondents, alluding to the insect theory, says: "It has not as yet been shown satisfactorily that any unusual insect has made its appearance upon the potatoes that have suffered from the rot, and this cause can be considered as little more than a mere conjecture. There are, indeed, several insects that, in almost all seasons, infest the potato plant more or less; but though when unusually present they may, to some extent, injure the goodness of the produce, either in quantity or quality, yet they have never been known to produce the decay in question, and it seems to me that I have seen these insects far more numerous in former years than last year."

(*b*) A second opinion attributes the disease to a *deficiency* or *excess* of materials for the progress or growth. We mean, by this general statement, to embrace under this head those who find this deficiency or excess either in the *soil* or in the *potato itself*. Thus Mr. Shaw attributes the *rot* or *rust* to *cutting the seed*, by which the skin is wounded and a perfect crop prevented. But, as the editor of the Maine Farmer says: "Potatoes have been cut for a long time without producing the disease; and why should it? Others, therefore, suppose that the seed has become so deteriorated as to be wanting in the requisites for producing a fair tuber or a full crop. But potatoes of the diseased crop have been planted, and no disease resulted." A writer in the Farmers' Cabinet, under the signature of *Chemico*, supposes the difficulty to be in *the deficiency of an alkaline basis*. He says: "It is well known that the substance forming the cells of all plants is a compound of carboniferous matter, with one or more alkalies, together with silex, &c. It is also well known that if the cellular matter is deficient in alkaline substances, &c., it is comparatively weak and unable to contain the matters deposited in it. It is well known, too, that the alkalies regulate the formation of the acids in the healthy vegetables, and that when there is not a healthy supply and a sufficient one of alkaline bases, the vegetable either contains a superabundance of acid, or its growth is impeded. In the former case the vegetable is not fit for culinary purposes. Now, I believe that, in the case of the disease of the potato, the cause is to be found in a deficiency of alkaline bases. This is manifest from the want of power in the cellular substance to perform its offices, and it is also manifest from the presence of acid in the potato. In consequence of this deficiency of alkaline substances, the potato plant forms an alkali peculiar to itself, which is very poisonous in its nature, and which I doubt not produces the fatal effect sometimes consequent upon eating the diseased potato." This view of the case is advocated to greater length in the letter of our correspondent, Mr. Thos. Crofts, of Wilkesbarre, Pennsylvania, which appears to contain the admission also that he is the writer above mentioned in the Farmers' Cabinet. His letter, addressed to the Hon. H. L. Ellsworth, on the supposition that he was still Commissioner of Patents, will be found with the others in the appendix No. 5, before mentioned. Professor Mapes, of New York, in the Farmers' Club, also throws out a suggestion that the rot may be owing to the *absence of copper*. *The deficiency or excess of ammonia* is also suggested as a cause by Mr. Weeks, of Vermont, in the Boston Cultivator, and the *want of starch* in the potato, by others.

The action of manure on the plant, and forcing its growth unduly, may

be ranged under that part of this branch which relates to excess of proper materials. Manures which are highly putrescent, and such as are apt to act too vigorously on the plant in its tender growing state, are said to be very injurious to its production. Unfermented manure is also ascribed, by some, as the great cause of the evil; but the fact is asserted, also, that the rot has prevailed where this condition did not exist. *Excess of moisture* is said to be the origin by "G. S.," of Pendleton county, South Carolina, in the Cultivator of May, 1845, page 150. He thinks that a superabundance of sap collects in the potato, and that this fact would be seen by cutting the tops, and that much water would be found to have discharged from the standing stumps. But as this is mere conjecture, and no particular experiment is brought forward to sustain it, it is unecessary to do more than mention it.

(*c*) *The influence of the atmosphere* is still insisted on by some. The advocates of this theory do not precisely define the limits which they would assign to the supposed cause. Mr. Freeman, of York, in his letter to the Boston Cultivator of September 25, seems to adopt this view. After adverting to the fact that in the previous year the rot appeared about the last of August, which he attributed to the very warm weather, with frequent but not heavy rains, which invariably cleared off very warm, he says: "This season has been the warmest for many years; the rains in this section commenced one month earlier than last year, say the last of July or the 1st of August; consequently the most of the potatoes, save those planted very early and of an early kind, were young and tender when these rains commenced." "The days and nights being very warm, thus greatly injured," as he supposes, "the plants, the rains being barely enough to wet the manure in the hills; and the sun came out hot, killing the vines, while the heat and wet were destroying the young and tender plant or tuber." Mr. Weeks, of Salisbury, Vermont, also, in the Cultivator of September 1, gives his theory on the action of the atmosphere as follows: "I am inclined to believe that the disease is caused by the atmosphere, chiefly operating on the earth in such a manner as to obstruct its natural circulation of sap, which prevents exhalations of the plant, and deranges nature's perfect operations by preventing the escape of the excess of ammonia which accumulates in the hill, and is held there in a state of unnatural confinement by the disease of the stalk and the crust which forms upon the surface of the ground, which makes the hill nearly air-tight. The ammonia in the hill engenders disease, which usually, under these circumstances, makes its appearance in the form of a blister upon the skin. In other cases the ground appears to crack near the root of the vine, so that the ammonia escapes so rapidly that the vine is killed at once," &c. As reasons to support his view, he alleges, first, on the observation both of himself and hundreds of others, that "where the land is manured with that kind of manure that is highly charged with ammonia, the malady is most fatal. Secondly, where the same land, side by side, is manured with manure so rotted as to have it smell, very little disease is found. Thirdly, the hardiest varieties of potatoes are not so liable to the disease as those which are more tender and feeble. Fourthly, that kind of compost possessing no smell of ammonia will invigorate the stalk and elude the disease." "Manure that is in a state of fermentation, when applied to the potato hill, or manure that will ferment, so as to exhale ammonia to any considerable extent during the growth of the plant, will be likely to engender disease," &c. "M.," of the

Indiana Farmer, after mentioning the appearance of the tops of the potatoes, (already quoted above) says: "I attributed it to too much wet, as they were situated where the water (when it falls copiously, as it has of late) stands for some time after falling." Mr. Lodge, also, in a letter read in the New York Farmers' Club, says: "Our seasons vary—sometimes very hot and dry, followed by heavy freshets and floods. Lands thus drenched, and not drained by proper deepening, and breaking the hard pan, must suffer, and will inevitably cause curl in the leaf, premature its growth, and stop the progress of the tubers, and in this tender state disease will follow." Mr. Townsend, of Astoria, in the same meeting, said: "I believe that this disease is owing to the seasons." Judge Van Wyck, also, in the same club, said: "Climate and seasons no doubt aggravate the disease. I found it existing three years ago on my farm in New Jersey, in a wet season; and in the next season, which was dry, worse still. This last season, which was very dry, the rot was worse yet. The editor of the American Farmer, remarking upon the views of "E. B." relating to insects, says: "We incline to the belief that the rot is to be attributed generally to atmospheric influences, an undue or premature springlike weather in early fall, causing the potatoes which are at a vigorous growth, though not fully matured or perfected, to begin to shoot or to grow, in manner as though they had been planted for the purpose. This premature process ferments the tubers to an incipient state of decomposition; and hence the withering of the vines, and the consequent deterioration of the crop." He states, also, that the same idea was thrown out by Mr. Gowen, of Mount Airy, in his report of crops in 1843, published May 29, 1844, in the American Farmer.

A. Robinson, in the Boston Cultivator of December 20, 1845, seems disposed to adopt the theory which explains the disease from the influence of the weather, &c. He says: "In the first place we know that the potato is a tender plant, and cannot withstand a great deal of hardship; we know, too, that the past season has been one of great extremes of heat, dryness, and moisture, and consequently unpropitious for the potatoes. I speak particularly of our vicinity, where the earth was so severely parched, wet, and dry, that we had nearly given up all hopes of a crop. After a very heavy rain it remained hot, while we had alternate extremes of heat and rain, which set the earth in a great fermentation, a state very injurious to some sorts of vegetation." Mr. Cole, of the Boston Cultivator, in a late agricultural meeting in Boston, (says the New England Farmer,) "thought the rot should be ascribed chiefly to atmospheric influence. He said that apples of various kinds had been affected in the same way. Jewett's fine red he had known for thirty years, and he had never seen it so much affected with rot as in the last autumn. He thought the atmosphere might affect various kinds of fruit, in the same way as it affects the potato."

From the above views it will be seen that the opinion of an atmospheric influence is one which has some, who are both scientific and practical men, in its favor. There is not, indeed, an agreement as to the manner in which the action of the atmosphere affects the result; but much is undoubtedly attributed by many to this as a great general cause of the evil under consideration. Even if it be not viewed as a *proximate* cause, it would be viewed by some as a more *ultimate* one. But such a fact would need a series of observations for more than two or three years to form a satisfactory conclusion, since coincidences might exist for two or three seasons without there being any thing of the nature of cause and effect, if we consider the words to

imply origination, or any thing else than the relation of simple antecedent and consequent.

(*d*) The *fungus* theory is probably, on the whole, the favorite one among those who have written on the subject in our country. It will be recollected that in the last report two letters were given of Mr. Teschemacher, of Boston, advocating this view. We learn that he still maintains the same opinion. In his letter to the New England Farmer, under date of November 19 last, he says: "The fungus that I have seen vegetates on and thickens the sides of the cells of which the potato is composed, which cells contain the grains of starch. The starch is not injured until the sides of the cells rotted by the fungus burst; the worms or maggots breed, and the whole finally becomes a mass of putridity, with an offensive fungus-like smell." He also fortifies his views by a reference to those of Professor Morren, of the University of Liege, and which will be adverted to when we come to the consideration of the disease as it has prevailed abroad. In a letter also received at this office from Mr. Teschemacher, which will be found in the appendix among other papers, he also considers the views adopted by the British professors, and urges the following objections against the atmospheric theory, which attributes the disease to the cold uncongenial weather. He says: "But quite decisive objections to this view are, 1st. That we have had a warm and dry summer on this side of the Atlantic, with more than a usual proportion of sunshine, and yet the disease has spread with equal fatality here. 2d. That they have had many such wet, cloudy, and cold summers before in Europe, without the appearance of this peculiar disease in the potato. It is clear, therefore, that this so called atmospheric influence is merely a name, without any distinct tangible meaning; and the evil of accounting for the disease by a mere name, such as an epidemic or atmospheric influence, is to stop all further inquiry and investigation either into the cause or remedy. If the seeds of the fungi were not there, the atmospheric influence could not cause them to vegetate; and if, knowing the nature of these fungi, we can destroy them or prevent them from vegetating, there is an end of the disease. Again: That the disease has increased immensely since 1844, gives a very strong natural presumption that it arises from the rapid and more widely diffused propagation of a vegetable fungus, the seeds of which, (spores) according to Professor Morren, are generated in inconceivable numbers." "That there are peculiar circumstances which favor the rapid propagation of particular fungi is certain, and equally certain that there must be circumstances unfavorable to it; and it is to the study and production of these unfavorable circumstances that we have to look for remedies." The writer in the Farmers' Cabinet, whose views we have already quoted as being that the disease is attributable to the deficiency of an alkaline base, has also a paper in the same journal, in which he attempts to show that, if the fungus theory be admitted, his views are still correct, inasmuch as he claims that the cause of fungi is the same defect of alkaline substances. He says: "A chemical analysis of the plants of the fungi tribe will show that they contain an extremely small proportion of alkali—smaller than any other class of vegetables. Upon whatever spot of ground the fungi make their appearance, *there* is a want of alkali," &c. Others are also strongly of the opinion that the evil is of fungus origin, but, as they offer nothing new, it is unnecessary to advert to their opinions.

It may perhaps be inquired, if the disease is fungus, whether, after all, there must not be something peculiar in the season, or the soil, or condi-

tion of the seed, to account for the fact that it should appear so strikingly, just at this time; and, therefore, if the fungus theory is admitted, whether we have pressed the investigation as far as we may, having arrived only at a *proximate* cause, while the cause of this fungus may deserve a further examination. Mr. Webber, of Charlestown, N. H., remarks, in his letter to the office, speaking of the fungus theory, "A supposition of this kind has heretofore been made in this country; but it seems possible that this may be merely a mistake of the effect for the cause. Decaying vegetables are almost uniformly the prey of parasitic or fungus growths. In the economy of Providence, it seems to be a law that there shall be no waste, and that, wherever there is nourishment, there shall be life to consume it and be supported by it, and that the decay of one race shall afford aliment to others. I hardly ever saw a rotten potato without noticing a fungus growth upon it; and potatoes that have rotted in low lands or in the cellar, from becoming water-soaked, presented no obvious appearance to the eye different from those that decayed in the manner under consideration; fungus growth was equally evident in both. Still, the supposition may be true; but other and different observations are wanted to establish it. The death of plants is, indeed, often seemingly, and sometimes probably really, owing to the attacks of insects and parasites; but there seems to be no good reason to suppose that the vegetable kingdom may not be subject to diseases as well as the animal, though the advances made in the study of vegetable physiology have not as yet made us acquainted with them; and the investigation of the subject is by no means as easy. Where so little is known, changes that are apparent are, by the prevailing disposition of the human mind to assign a cause for every thing, laid hold of as causes, though they may be but coincidences, concomitants, or even results; and thus the appearance of parasites, whether of an insect or vegetable nature, upon a decaying plant or tree, are apt to be considered the cause, when, perhaps, they make their appearance only because the tree or plant is unhealthy; and perhaps, at any rate, deriving so much of their nourishment, as plants do, from the atmosphere, and the influences of light, heat, and electricity. In modifying and directing what may be considered their vital actions, it would seem strange if they should not be liable to suffer at times severely from sudden changes of atmospheric influence; and, where so widely spread a destruction as the one in question has taken place, till something more definite can reasonably and philosophically be shown as a probable cause, it would seem as well to look at some such change as the real cause. Such, indeed, has been the opinion of many; hough of the precise nature of that change they are ignorant."

The above remarks, we think, are entitled to attention, and the views expressed coincide much with those we are disposed to entertain in relation to the subject under consideration.

9. The great practical question, however, is, What is the best *remedy* for the wide-spread evil? So far as the knowledge of the cause may aid to suggest the remedy, it is desirable to know respecting its origin. But a remedy may ofttimes be found by experiment, even allowing that the true *theory* of the source of the evil is still unknown. Most of the remedies, however, correspond with some of the views as they have been given above. In some instances, the same remedy having been found efficacious by the advocates of opposite theories, its fitness is accounted for so as to favor their own peculiar views.

There is some considerable diversity, also, respecting the actual utility of

substances supposed to counteract the origin or progress of the disease. Some persons, in one set of circumstances, have tried a remedy and recommended it as sure. Another, however, informs the public that it will not answer. This diversity, it is probable, might often be accounted for by the different condition of the soil, the crop, or the season, &c., in which the experiments are made. We shall pursue the same course we have adopted above, and present the various suggestions which have been made, referring as before to the appendix No. 5, where the papers from which we draw our quotations may usually be found.

The advocates of the *insect* theory recommend a number of articles to prevent or remedy the evil. The editor of the Boston Cultivator, alluding to the opinion of Mr. Burril of Stockbridge, says: "We have understood that house-ashes spread on the hills around the vines after they have grown a few inches from the ground, is not only a remedy for the blight, but greatly facilitates the growth of the potato on some soils." "E. B." of Pompey, whose statement has already been given, speaking of the vines, says: "As a remedy, I cut off the diseased part and destroyed all the flies I could. About 10 o'clock I sprinkled soap-suds upon one small patch, and no flies were found upon it at night, though many were found upon another piece that had not been showered. An hour before sunset I sprinkled the suds left from washing upon the whole." Dr. Stebbins, to guard against the insects he discovered, sprinkled his vines with tobacco liquid, and found it to be an effectual remedy. Mr. Patillo advises the use of sulphur. Those who attribute the disease to any *excess* or *defect* of any *chemical* element, of course recommend the supply or withdrawal of that substance or constituent part. Thus Mr. Croft, who imputes the disease to the want of a sufficient alkaline base, recommends the use of potash, or some other alkali. He says that "an alkali will cure the rot in potatoes in two ways—first by strengthening the cellular tissue, thus preventing the rupturing and consequent disorganizing of the potato, which would result in decay and death; and, secondly, by neutralizing the carbonic acid, and thus destroying the infectious principle." He also alludes to experiments made by Mr. Teschemacher and others, and says, in his letter to this office: "If, therefore, potash be not present in sufficient quantities, we may reasonably expect that the potato will be impeded in its growth, if, indeed, that growth is not totally arrested; if, while the growth is impeded, the supply of carbonic acid be great, and the potato has an opportunity of absorbing it, such carbonic acid, by its infectious properties, will disease the potatoes, (even if there be a comparative drought at the time,) and such disease, if it be not checked, will destroy the potato. Carbonic acid loses this infectious property when it becomes a salt by union with an alkali, and is then rather beneficial than injurious; for if that alkali be potash, the potato plant will assimilate both the potash and the carbonic acid; and, other conditions being equal, the result will be a large and healthy growth." "The foregoing remarks," he adds, "would lead us to suppose that, by supplying the alkalies in sufficient quantities, we should at least save our potatoes from the rot." He then alludes to numerous cases which he quotes from the last report of this office, in which the use of lime, ashes, plaster, &c., is mentioned as having been of great advantage, and claims that his view is thus abundantly sustained by actual experiment. It is unnecessary to do more than refer to the letter itself, in the appendix, for the further elucidation of his views, and

the action of the remedy he proposes. His arguments must be allowed to be ingenious, and perhaps plausible.

For the same reason, adverting to the fungus theory and his own view of fungi, as caused by a deficiency of alkalies, he says: "The fungi being composed principally of carbon, oxygen, and hydrogen, feed upon carbonic acid and water chiefly; and, consequently, if lime or potash be added to the soil where they grow, and the carbonic acid be thereby changed into a salt, the fungi have nothing to feed on, and do not attack the potato. On the other hand, when there is *not* sufficient alkali given to the potato crop to cause the carbonic acid in the potato, is in its own form of carbonic acid, and as such the sickly root offers the proper food for the fungi, and it avails itself of it—then unfortunately for doing so, it brings down upon itself the charge of being the cause of the potato disease."

Mr. Weeks, who holds that the disease is caused by the excess of ammonia being prevented from escaping, urges that "some compost or other substance should be used which will strengthen the stalk, and enable it to elaborate the sap and convey back from the air to the root nutritive elements, so necessary to the hill, in order to preserve the tubers there." We have already quoted the course he adopted in his experiments, which proved successful, of using differently manured land, together with lime; and afterwards, when the plants were out of the ground, salt, unleeched ashes, lime, plaster, &c.

"Philo," of Portland, also believes the disease to come "from an over action in some part of the plant, and a minor action in some other part. And it is very evident that the roots cannot penetrate the hard, unbroken stratum, to obtain moisture." He advises deep ploughing, so that there may be depth enough of earth to allow the descending roots to gather moisture through the season, to act in concert with other roots and the leaves, thereby preserving a healty state of the plant.

The theory suggested by "G. S.," of Pendleton county, S. C., in the Cultivator, of the too great moisture in the tops, is also accompanied by the advice to cut off the tops near the ground, as the appropriate remedy. Another person likewise recommends the cutting off the tops to preserve the tubers before the disease has passed to them from the vines.

The following is the view lately communicated to the New York Farmers' Club, by Nathaniel Sands, of New Windsor, Orange county, New York. He says: "I have found that by planting potatoes as early as possible, I have good crops. The tops perished in August. I let the potatoes lie in the hills till September, and they were perfectly sound. I have seen some disposed to decay, upon which I put lime, and these were saved from further rot. A neighbor of mine had a pond, from which he let the water flow upon his potato field in dry weather. For ten years past he has always had sound potatoes." To prove the efficacy of this watering of his potatoes he had another field which was left dry, and there his potatoes rotted. "The tops of my potatoes totally died in August, but the potatoes kept well in their hills till dug in September. What I call late planting, is late in June. I do not let my planted potatoes be in immediate contact with the manure in the hills. I find that when rain comes and soaks through the soil and manure, the potatoes do better than when in close contact with the manure."

A writer in the Bangor Courier, who writes over the signature of "A Glenburn Farmer," who supposes that the potato had no internal disease,

but was made to rot by an external influence, which he says was *fermentation*, recommends the drying of the potatoes by exposure to the air and sun, &c., as a mode of preventing the spread of the disease. The editor of the Maine Farmer, however, controverts this view, and alleges that if exposed to the sun and air, the tubers will become watery, waxy, and acrid of taste. His view is, that they should be stowed away, with as much sand or soil among them as could conveniently be done.

In the last report mention was made of lime and plaster, ashes and salt, as remedies approved by some persons. We find instances of these as having resulted favorably in the different agricultural journals.

Mr. Teschemacher, in his letter of the 19th of November last, in the New England Farmer, again recommends it. He says: "I think that salt, lime, and several chemical compounds, will destroy the disease. I prefer salt, because, when mixed in the soil, it may get into the juices and circulate through the whole plant. Lime or lime-water would do the same to a certain extent, but it is far less soluble than salt." He then adverts to the fact that salt has been used, and near the seashore, without effect, which he supposes may arise from there not being a sufficiency of saline matter in the sea-weed used, &c. In his letter to the office, already referred to, (and for which see the appendix,) he enters more fully into the question. He says: "The truth is, as respects the application to potatoes dug, is propably that if the disease is already under the skin the salt cannot penetrate, and then, unless the brine were very strong, the moisture of the solution may accelerate the progress; but I do not believe that an entirely untainted potato, if covered with a strong briny solution, will ever receive the disease. The instances where salt has been used in the soil, and the potatoes have escaped, are not unfrequent. After numerous inquiries, I have heard but one solitary exception, where six bushels to the acre had been *harrowed* in, the potatoes had the rot the same as those without salt. I admit that this alone would be fatal to the virtue of the remedy, were it not for one circumstance. I found, on inquiry, that the soil was the stiffest and most unyielding clay, and into this water cannot freely penetrate, much less water thickened with salt; the experiment, therefore, does not prove the use of salt, for, in every probability, it was washed from the surface, or never penetrated to the roots of the potato." There are several instances, he adds, "in which the application of chlorine gas has clearly destroyed the disease; but this application on a large scale is impossible, and, besides, is liable to very dangerous and fatal accidents; but salt is a mixture of chlorine and soda." "Unslacked lime will also destroy this fungus, and must, therefore, be a most excellent addition to the soil, with salt; but lime is not so easily caused to circulate in the juices, except as lime-water. Then the acids in the plant would quickly saturate it and change its nature; in addition to which, it attracts carbonic acid from the atmosphere, and becomes a carbonate of lime, in which state its powers on fungi are very questionable."

With reference to the preparation, &c., of the next year's crop, Mr. Teschemacher further says: "I have given much study and reflection to the subject, and the result is the following recommendation: Let the potatoes intended to be planted be selected with the greatest care, with the fairest and clearest skins; rejecting all such as have small, dark, soft, pustulous looking spots, which are often not larger than the head of a pin; powder them over liberally with fresh quick-lime, and keep them as warm and as dry as possible. It is, however, indispensable that the warm h be a dry heat. The

spot for planting should be a good loamy virgin soil, or a spot that has not been broken up for years, and as dry and well drained as can be had. Do not use any manure, but put in guano if so minded, as it is not possible that the seeds of the fungus can exist in it, whereas manure may be a fertile source of them. Just before planting, plough both lime and salt into the land, then steep the tuber in a strong solution of brine, to which a little bluestone (sulphate of copper) may be added, and commit them to the soil. I have not said anything respecting the quantity, as this must depend on the soil."

We may add here some instances in which salt, lime, &c., have been said to be used, and the effects of them. In the Ohio Cultivator it is stated, from the Akron Democrat, that the Rev. Mr. White, of that place, on removing some potatoes, filled two barrels, one of which had been used for flour and the other for salt, from the same heap, and put them side by side, covered with the same boards. After some time those in the salt barrel were found to be perfectly sound, while those in the flour barrel were all, or nearly all, rotten. "This," says the Ohio Cultivator, "would go to prove what has before been asserted, that salt, in some cases at least, is beneficial in preserving potatoes from the rot after harvesting. Lime also has been found useful for this purpose; but more experiments are needed with both before the question of their utility can be fully settled." Again: "*Lime the medicine for potatoes.*—Two fields of potatoes, side by side, in this village, one dressed with tan-yard manure, in which was considerable lime, received no blight or rot. In the other field, with common barn-yard manure, the tops were early blighted, and a considerable portion of the potatoes rotted."—*Brunswick* (*Me.*) *Pioneer.*

In the New York Farmers' Club, of September 2, 1845, Mr. Thompson, of Astoria, says: "I used lime freely on my potatoes, and they rotted." Mr. Fleet said: "I have remarked many experiments made with lime—some good and others bad." As the potato is an exhausting plant, he did not understand why the second crop should have been larger than the first; but, on looking at the analysis of the potato, thinks it is attributable to the salt; and believed, further, that 20 bushels of unleached ashes to the acre would have increased his crop to 600 bushels per acre. The analysis of the potato, as he quotes it from Professor Johnston, is as follows:

	Roots.	Tops.	Total.
Potash	80.5	327.3	407.8
Soda	46.6	0.3	469.9
Lime	6.6	517.0	523.6
Magnesia	6.5	70.0	76.5
Alumina	1.0	0.2	1.2
Oxide of iron	0.6	0.8	1.4
Silica	1.7	196.0	197.7
Sulphuric acid	10.8	16.8	27.6
Phosphoric acid	8.0	78.3	86.3
Chlorine	3.2	2.0	5.2

In the same club, November 4, 1845, Mr. Colt, of Paterson, writes: "I have cultivated old grounds, and used on them a compost—one of salt, one of lime, one of plaster, and two of wood ashes; and then the same compost, adding one of guano mixed. There was very little difference in the result—rather in favor of bone dust and guano. There was no rot. On new

ground I made use of salt, ashes, and plaster; and on this ground I have the best potatoes, but no rot in either. From this I came perhaps to the wrong conclusion, that salt, lime, and plaster of Paris will prevent the rot." Mr. Hammond, of Conesville, in the April number of the Cultivator for 1845, says: "Lime has been said to be a preventive of rot. It proved *not* to be so in this case. Some coarse lime had been spread on a part of the field. Some hills, where the lime happened to be scattered, were particularly examined, and found to be much more rotted than where nothing was put. Plaster was used in most of the crop. Two rows were left through the field without plaster. No difference could be discovered between these and other rows in the condition of the potatoes." E. V. N. Dox, of Lafayette, in Oneida county, New York, in the February number of the Cultivator, says, in reference to the use of salt for the potato crop: "Three years ago I had a field in excellent heart planted with potatoes, which gave an excellent crop, averaging 300 bushels to the acre. The next year it so happened that it became necessary to plant the same field with potatoes, but I feared lest the worms should destroy the crop, as they appeared quite numerous at the first digging; but I proposed to remedy this by sowing salt, which I did about a fortnight before planting, at the rate of a barrel per acre." He states that he supposed the salt would kill the worm, but it did not. The crop, however, on digging, gave 420 bushels to the acre—far beyond his expectations.

The experiments of Colonel Clark, as stated by him to the New York Farmers' Club, and also in his letter to this office, deserve notice, as showing the success of the remedies he adopted for the diseased potato. He says that he selected a lot which had been rejected as unfit for use. These he divided into 3 parcels. "No 1 was subjected for 12 hours to a weak solution of chloride of lime; No. 2 to a saturated solution of recently burned lime, (quick-lime;) No. 3, in a moist state, was sprinkled over with quick-lime water slacked to dryness. Nos. 1 and 2, after being thus treated, were spread on a brick hearth, and No. 3 was suffered to remain covered partially with dry caustic lime, and all of them so suffered to remain for 6 weeks, when they were examined, and the disease found to have been wholly arrested. The potatoes in Nos. 1 and 3 were somewhat shrunk, probably from the too caustic treatment which they had received; but No. 2, or that which had been steeped for 12 hours in lime-water, were plump and good, and where the diseased portions or blotches came off with the rind." "The parcel from which he took the potatoes on which he experimented," he says, "continued to perish, and were finally thrown away as worthless." He adds: "Exposure to the atmosphere, in a dry place, may have had a beneficial effect; but as the disease is, beyond doubt, occasioned by *fungi* of a very delicate texture, these were destroyed or decomposed by the acrid substances to which they were exposed. If mistaken in the character of the disease, and it should ultimately be found to result from the depredations of animalculæ, the cure may be ascribed to the same cause. The results of my experiments induce me to believe that the absence of a sufficient quantity of limestone (carbonate or phosphate of lime) in soils, is the cause of the disease in the potato. If it be owing to other cause or causes, the remedy indicated, it seems to me, is the free use of lime-water made from lime slacked to dryness, or of unbleached ashes, at the planting or first dressing season of the potato; and I suggest to farmers, who may have been sufferers from this wide-spread pestilence in their crops, to try whether

a judicious use of these materials may not prove a corrective for or a prevention of this disease."

We have thus presented the substance of the accounts before us, as relates to the appearance of the potato crop of our country, and the views entertained respecting the cause and remedy of the so-called potato rot. We do not feel sufficiently satisfied, from this examination, to offer any decided opinion as to the cause or origin of the evil. There are, however, some deductions which we think we are authorized to make, and which may serve to embody the results of our somewhat extended consideration of the foregoing particulars.

1st. That all the detailed appearances cannot be considered as legitimate effects of any *one* cause.

2d. That *many* of them are *merely accidental*, and that their presence or absence would prove nothing as to the nature of the cause of that evil with which they are associated.

3d. That we have reason to believe that the *cause itself*, and its *mode of development*, have often *been confounded* together, or mistaken one for the other.

4th. That there is great reason to doubt whether the *immediate* effects of the latent cause have been so far subject of observation, that an accurate and sure opinion can be formed respecting it.

5th. That, whatever be the cause, there are different *stages* of its development—*degrees* of its power; and that these depend on a variety of adaptations in the circumstances of the crop.

6th. That the *rapidity* of *development* also corresponds with the aid derived from extraneous circumstances; and hence some, if not all of the evil results may be remedied.

7th. That it is doubtful whether any remedy suggested has been sufficiently tried to enable us to pronounce it a *certain* or *sure* one.

8th. That it is important to study more accurately the influence of *soil*, *seed*, *culture*, *temperature*, and *condition of the atmosphere* on this crop; and that it is only by a series of careful and discriminating observations that we can clearly decide on the probable origin and most fitting remedy.

9th. That many of the preventives or *checks* recommended have, in their favor, so good proof of a *degree* of efficacy, that, till better are discovered, they may be safely adopted, suitable regard being had to the similar or different circumstances of their application.

We believe there has been, as usual, injury sustained to the potato crop of the United States by the prevalence of ordinary and common causes, such as must be expected, more or less, every year. We do not doubt, also, that there has been an extraordinary loss of this valuable product; but whether it be owing to some before known cause, which, from the peculiarity of the season or some unknown circumstances, has exerted an unusual influence, and thus a new development, or to some hitherto unexperienced cause till within a short period past, we cannot say. Whatever it is, its progress is not yet fully traced, and it is only till more light shall be shed on the subject that we can confidently pronounce in favor of any one theory; and it seems probable that there is a combination of the views that have been suggested necessary, in order to account for its various phases, as we cannot resolve all the great features into one, entirely independent of all others. It so happens, however, that we have it in our power to make a comparison

as to the aspect of the evil among ourselves, and in those countries where it has prevailed.

The prevalence of the evil in Great Britain and on parts of the continent, during the past season, has led to numerous statements or accounts respecting the appearance of the vines and the tubers, and occasioned considerable diversity of sentiment even among the learned and scientific, as well as the simple practical farmer, respecting the origin and cause, and the best method of treating it. The supposed causes, however, are much less in number than in our country, at least so far as we have been able to ascertain them. We have seen scarcely any attempt to trace the evil to insects; but nearly all writers seem either to consider it atmospheric, from over-cultivation, deterioration, or fungus. It is called by a variety of names, as the potato blight, rot, disease, gangrene, cholera, murrain, &c. The usual name is the *blight*, or *rot*. The appearances of the vine and the tuber are generally described in very similar terms, and these correspond nearly to the same already heretofore given in this country. It seems to be thought that traces of it have been heretofore seen in some places, but these were not sufficient to excite particular notice till within the last season.

The *earliest* mention we find of its appearance in our English periodicals was in the Isle of Wight, and the Isle of Jersey. This was about the 11th or 12th of August last; and perhaps somewhat earlier, for we find some difficulty in fixing its precise date. It is noticed by a correspondent from the Isle of Wight, but with no date of time, in the London Gardener's Chronicle of August 16; another from the Isle of Jersey, in the same paper, of August 23; and also by another in the Isle of Guernsey, in the Mark Lane Express, of August 25, 1845. From the southern part of England, it rapidly passed through Devon, Cornwall, Sussex, and Norfolk, towards the north, and finally, in the course of two or three weeks, we learn of its ravages as having commenced in Ireland and various other parts of the Kingdom. It may be useful to quote from the description thus early given of the appearances. Dr. T. Bell Salter, of the Isle of Wight, in a letter to the London Gardener's Chronicle, edited by Prof. Lindley, says: "A blight of unusual character, which almost universally affects the potatoes in this island, having been, within the last few days, repeatedly brought to my notice," &c.—he then goes on to describe the appearances, as follows: "The first appearance is a dark spot on the margin of the leaf, which withers the leaf and spreads rapidly to the stem. The discoloration soon extends along the stem, in the course of the vessels, and the whole plant rapidly becomes black; so that within the course of three days after a plant has been attacked, it has become totally destroyed. With this appearance in the upper part, there co-exists a fatal change in the tubers; they become likewise spotted at first near the eyes, on the upper surface; the cuticle separates, the substance becomes friable, and the change soon spreads through the whole potato. All situations, high or low, and whatever the nature of the soil, appear to be equally visited. The attack on the plant appears invariably to commence in the leaf, and not in the stem; and the spot commences at the margin, corrugating the leaf as it spreads. It is black on the upper surface; but on the lower surface, though black in the centre, it is whitish or gray on the margin, but neither minute insects nor fungi can be seen with a strong lens. That, as regards the green portion, the leaf is affected before the stems, I am quite clear; but the question arises, is the disease in the root and tuber the cause or consequence

of the above change?" He supposes it to be the consequence, especially from one case, where, from ripeness, the green leaves were on the point of withering when attacked. The affection did not at all extend to the roots.

He next describes the change in the tuber, and says: "The first appearance much resembles a severe burn, the root turning gray or ash-colored, and the cuticle coming off. The taste is pungent and nauseous as the disease advances." Another writer says: "I yesterday saw a piece of potatoes that look as if they had all been scorched, although but two days before they were looking as healthy as need be. They become attacked with small brown spots, and in less than forty eight hours they are quite burnt up, and the smell arising from them is most disagreeable. The potatoes, when cut into, have the appearance of being frost-bitten," &c. In the Chronicle of August 23, Richard Gifford writes from Jersey that the disease appeared there about three weeks before—about August 1st; that the places most affected were under the hedges and in the coldest part of the fields. Another writer in the same paper says: "The centre of the plots has been first affected;" that "the haulm smells remarkably like new-made hay, and the whole mischief above ground is done in three or four days." Another writer mentions that in one night the leaves of potatoes had turned as if struck by frost." A correspondent, also, of the Mark Lane Express of August 25, writing from Guernsey, under date of August 16, says: "Up to Monday last, August 11, the promise was for the most abundant crop ever known; the whole looked healthy; in one night the mischief was done—the whole of the stalk and leaf turned as black as your hat, and the potatoes rotted in the ground." Other particulars, mentioned by different writers, are, that only a small portion of the potato was affected in some two or three places; roots fair to the eye when boiled, were as if frost-bitten, and were uneatable; tubers nearest the surface affected. In Sussex, "first appearance in low and cold situations; then hills and slopes; the site of an old stone pit, on high ground, clearly traceable in a large field by first appearance of disease and decay of potatoes." In Folkestone "the most perfect drainage does not cure, but accelerates the evil." In some cases the early potatoes were the most affected; but in St. Helier, Jersey, the attack is said to have taken place about the 4th or 5th of August; the barometer was very low, and had been so for some time; the electric matter also filled the air from the 22d July, without thunder; early and late potatoes were equally affected; the places where they were most affected last year suffered a month earlier this year." From others, also, we learn that the sound potatoes are most remote from the haulm, and bad ones just at the bottom of it, the ends being attached to the haulms." Mr. T. P. Elliot mentions, before the disease was announced in a part of Ireland, that there had been a disease there for three or four years past which had done much mischief; "instead of commencing above ground, it seems to commence with the decay of the old set." The editor says that it is "only a mild form of the murrain." In Cornwall a writer mentions, "in the early part of the preceding summer we had two, and only two, excessively hot days. The heat was intense; it came on suddenly and lasted only forty eight hours;" a crop of potatoes was noticed the day before this accession of heat as thriving and in perfect health; they were of recent growth, and the stalks had not sprouted. On being visited after the hot days, the plants had all made very long shoots of leafless stalks, and this rapid growth had taken place in forty eight hours. On the fall of the temperature the plants became sickly, and were soon blighted. Another writer says, that in June, when digging up early pota-

toes, before there had been any appearance of disease even in the haulm, "there were left on the surface, fully exposed to the weather, sixteen potatoes, twelve of which are now found to be infected, the most exposed portion of the tuber being the worst." Another writer states that the disease was "first established by means of the haulm on that end of the potato, which henceforth assumes a darker color, at first, for a week or two, merely on the surface; this, by degrees, spreads to the eye end of the potato; and it is when established there, that the chief work of destruction occurs. Shortly after this the character of bruised flesh appears," &c. "I have not a doubt on my mind that this mildew commences with the leaf, like other mildews; and breaking up the tissue there, which is extremely delicate and watery, compared with other mildew subjects, induces the gangrene, which, finding a proper nidus all the way down the stem, descends rapidly through the stem into the potato, the cellular tissue of which, in the interior, affords as ready a facility for the spread of it." Another writer mentions that clay soils escaped best, but that in the porous green-sand formation it proved the worst. Another still says that sward potatoes are best. Another writer, in the Mark Lane Express, describes the aspect of the potato as follows: "The disease apparently attacks the plants in the fibrillæ of the roots, and where the root passes into the tuber or solid bulb of the potato. An interruption having taken place between the supply and the demand of the living plant by the decay of the root and its fibrillæ, its stalk quickly droops and withers in proportion to the progress of the malady. The thin outer coat of the potato may now be perceived roughened and thickened in one or more patches, and these, when cut through, show that the internal structure of the tuber is altered, the change commencing immediately beneath the cuticle or outer skin; the pulp is changed to a rusty brown color, like a bruised apple, in thickness varying with the intensity and duration of the disease; eventually the structure of the whole potato is converted into a reddish brown, half rotten mass."

In some parts of Ireland, great complaint is also made of the intolerable effluvia proceeding from the fields, so that persons could with difficulty be obtained to dig the potatoes. In some parts of the country, the strong soils are noticed as being much the most affected; while the potatoes on the lighter ones escape with less damage.

Such are some of the accounts which are given of the potato rot in Great Britain; and we think that, comparing the descriptions with those which were given in 1844, and during the last season of the disease prevalent in this country, we can scarcely entertain a doubt that it is of the same nature with that which has occasioned so much alarm among our own farmers and the community generally where the crop is considered an important one. It is therefore desirable to know what are the views of scientific and practical men in Great Britain as to its nature and origin, as well as the remedies best adapted to prevent its future appearance and progress. We are favorably circumstanced in this respect, as we are enabled to refer to the opinions of such men as Professors Lindley, Lyon, Playfair, Johnston, Buckland, as well as many practical and observing farmers and gardeners. The English papers are full of communications on the subject, but we shall confine ourselves principally to those which we find in the agricultural papers of high standing, and we have thrown in an appendix (No. 6) a variety of extracts, which we have quoted for the purpose of presenting the view here given of the disease in that country. The *theory* most generally

adopted by the scientific men of Great Britain is that which attributes the disease mainly to the *peculiarities of the season.* Some appear, however, to adopt that of the fungus; and others ascribe the evil to over cultivation and deterioration of the seed, &c.

On the first announcement of the disease, Prof. Lindley, editor of the Gardener's Chronicle, gives the following statement of his views: "The cause of this calamity is, we think, clearly traceable to the season. During all the first weeks of August, the temperature has been cold from two to three degrees below the average; we have had incessant rain and no sunshine. The potato absorbs a very large quantity of water; its whole construction is framed with a view of its doing so; and its broad succulent leaves are provided in order to enable it to part with this water. But a low temperature is unfavorable to the motion of the fluids, or to the action of the cells of the plant; and, moreover, sunlight is required in order to enable the water sent into the leaves to be perspired. In feeble light, the amount of perspiration from a plant is comparatively small; in bright sunshine it is copious; in fact, the amount of perspiration is in exact proportion to the quantity of light that falls upon a leaf, &c. During the present season, all this important class of functions has been deranged. The potatoes have been compelled to absorb an unusual quantity of water, the lowness of temperature has prevented their digesting it, and the absence of sunlight has rendered it impossible for them to get rid of it by perspiration. Under these circumstances, it necessarily stagnated in their interior, and the inevitable result of that was rot. If the first days of July had not been suddenly hot, it would not have happened; if we had had sunlight with rain, it would not have happened; and perhaps it would not have occurred had the temperature been high instead of low, even although the sun did not shine, and rain fell incessantly. It is the combination of untoward circumstances that has produced the mischief. Although we first see the symptoms of the disease in the leaves, and then in the haulm, yet we believe that it commences under ground, in that part of the haulm which is just above the old set; there, water collects the most; there the temperature is the lowest, and there the old set itself, acting like a sponge, and itself decaying, feeds the live stem with semi putrid matter."

In answer to the objection that potatoes thrive very well when summers are usually unfavorable, as the last, he says: "The potato then grows slowly; its tissue becomes thoroughly organized as it proceeds, and it is not liable to be acted on by accumulated moisture; no predisposing cause exists. But in England the potato was predisposed to take the disease, by the unusual warmth of the beginning of July, suddenly succeeding a period of cold ungenial weather. The potatoes grew very fast; their tissue was soft and unconsolidated, filled with azotized matter, as all such tissue always is, and peculiarly liable to run into a state of rottenness." Again, in the next week he repeats the view, and his belief that the cause is excessive wet and a low temperature acting upon the debilitated organization of a haulm, which sudden warmth has forced into preternatural vigor. Alluding to the idea that the spot on the leaf is the cause, that it is cold or some other thing acting on the foliage, that has caused a disease which spreads downwards, he adds: "If we may be certain of anything when considering the obscure phenomena connected with vegetable disease, we may be certain that this is not so. The evil always begins next the old set, and under ground; then the haulm becomes brown, and rots; the spots in the leaves

are merely the symptoms of the underground malady." He also states that cucumbers and gourds are similarly affected; and others, too, as we may here say, mention the same disease as reaching dahlias, onions, turnips, and carrots.

Again, in his next number of the Chronicle, alluding to the attacks of a kind of mould mentioned by a correspondent, he says: "This is only what was to be expected; for as soon as living matter loses its force, as soon as diminished vitality takes the place of accustomed vigor, all sorts of parasites acquire power, and contend for its destruction." He subsequently renews his declaration of confidence in his original opinion, and states a similar view to be taken among the Belgian cultivators, with the exception of Professor Morren, and says: "It is true, that a minute fungus has made matters infinitely worse; but that is, we quite believe, a *secondary* cause."

In the report of the Irish commissioners to examine into the disease in Ireland, &c., of which Professors Lindley and Playfair composed the majority, they attribute the cause to the season, and say: "Without pretending to decide what that cause really was, we may state that it seems to be connected with the cold, cloudy, ungenial weather which has characterized the present year over the north of Europe—conditions highly unsuited to the constitution of a plant which, like the potato, is a native of a warm, dry, sunny country, and insufficient for the ripening of the tubers. Without adverting to the solitary cases which require to be examined with more care than we have the means of giving to them, we may state, that amidst the mass of conflicting evidence which we have obtained, the following facts appear to be established: 1. That potatoes planted early in the season are more healthy than those planted later. 2. That the crop has suffered less in dry, elevated, sandy districts, where the influence of the season was mitigated by the slowness of growth, as compensated for by the natural warmth of the soil. 3. That the late varieties of potatoes are more diseased than the early ones. 4. That the present disease seems to be confined to the northern parts of Europe and North America, and to be unknown in the countries to the southward."

Another writer, who also attributes the evil to the season, says that in certain states of the weather the potato will become subject to morbid formations; and these, unless means are adopted to prevent their development, will soon show themselves by that corruption or rottenness which during the present season has been so prevalent. This disease sustains, then, the same relation to the potato as scrofula to the human species; it may be considered as partly resulting from constitutional defect, and partly from external causes.

Another, still, says: "Having examined the tubers infected with the prevailing disease, I have scarcely a doubt left upon my mind that it is that moist ulceration, *gangrena saniosa*, to which all bulbs and tubers are liable if exposed to ungenial circumstances at the time when their ripening processes should commence. He instances the cases of the tulip and hyacinth. At an agricultural club in Hadleigh, after a full discussion, it was resolved that "the failure is entirely owing to the season having been unsuited to fully perfecting the tubers of most of the varieties of the potato." Mr. Teschemacher, in his letter to this office, objects to the views of the British professors above stated, from the fact that the disease has prevailed here in a warm dry summer, and that, though we have had many cold, cloudy summers before, we did not suffer from the disease.

Some in Great Britain are strongly of the opinion that the seed has been injured by *cutting*, and otherwise deteriorated by *over cultivation.* One person says, that, "from its earliest appearance having been in the southern parts of the island, and the early sorts suffering most, it would seem that the mildew requires an elaborated state of the sap in the plant to facilitate its progress, as is the case with the pea mildew." It is suggested by another, that the disease is the result of the chemical changes necessary for the formation of starch, albumen, and other inorganic products, not having been produced in the proportions necessary for assimilation. It would appear that the peculiarity of the weather the past season has been so great as to cause almost every one to fix upon this as the *primary* cause of the evil. Thus, from Scotland, one person says: "This year the potato crop suffered severely from the cloudy and extremely cold and wet season—the temperature, especially in high districts, frequently bordering on frosts so early as from the latter end of July to the end of August, and subsequently." Again, in Peebleshire: "From the general nature of the disease, there can be no doubt whatever that it is produced from some general cause; and, without hesitation, we attribute it to the cold, wet, and ungenial season. We find, by taking a potato of the soundest description, and allowing it to remain for two or three days amongst earth over saturated with water, that the same disease is produced which is now so prevalent over all Scotland. Until such a time as we began to raise new varieties from seed apples, such a thing as failure or disease was never once heard of; and to the result of this experiment we in no small degree attribute the deterioration of the late potatoes."

A communication from Tweedside, in the Mark Lane Express of November 24, offers the following suggestions in favor of the view that the disease was in consequence of the peculiarities of the season: "During almost the whole of the time that the young potato was swelling into size and advancing into ripeness, the quantity of wet in the ground and the absence of sunshine were peculiar; and these, operating upon the potato in the tender stage of its growth, I am convinced are the causes of the disease by which it has been affected. I am led to this conviction by the following circumstances: 1st. In narrowly watching the taking up of potatoes grown in a dry deep loam, upon a sandy sub soil, I observed that those which were placed in a horizontal circle round the stem and near the surface, or partially bare, were not affected at all. 2d. Where the plants had occasionally penetrated deeper into the soil, and had produced one or more potatoes at the depth of eight or ten inches from the surface, those at that depth were invariably affected, while those placed nearer to the surface, and attached to the same stem, were free of disease. 3d. In thin turfy soils, or thin adhesive clay, upon an impervious stratum, the potatoes were necessarily placed in a position where the wet was lodged between the soil and sub-soil, and these I invariably found to be affected. 4th. In these soils potatoes lying close to the surface, or uncovered, were generally sound."

Erasmus Wilson, F. R. S, in a letter to the editor of the London Times, of September 23, gives the following opinion of the condition as well as the cause of the rot in potatoes. He says: "The real cause of the destructive changes at present taking place appears to be the *unripeness of the tuber*, and the consequent *imperfect elaboration of its juices.* When examined with the microscope, the cells of the potato are found to be not more than half filled with starch cells, (many of which are incomplete;) the

remaining portion of the cell being filled with water. Hence the actual condition of the potato may be stated as follows: 1st. Deficiency of starch; 2d. Imperfection in the tissue of the cell walls; and, 3d. Excess of water; to which may possibly be added, imperfectly elaborated starch. As a consequence of the imperfection of the tissue of the cell walls, and its state of maceration in a superabundance of water, it falls speedily into decay; the change beginning at the surface and proceeding inwards, and being indicated by a brown discoloration of the cells. The starch cells, which are at first unaffected, are soon enclosed in the decayed cellular tissue, and, becoming involved in the decay, are thereby destroyed."

Mr. Crossthwait, in the Mark Lane Express, of December 8, supposes the disease to have arisen from *excess of moisture* in the tuber. He says that he believes the redundant fluids of the potato press towards the outer rim, and not finding a vent, the disease commences, like a bruise, round the rim, or in the weakest part of the potato. His remedy is to cut the tuber across, and thus allow the superfluous moisture to escape, and the disease is arrested. In proof of this, he alleges some experiments made by him, and which he found to be successful. Those potatoes, also, which were accidentally cut by the spade while they were dug, almost entirely escaped. He likewise recommends that all the small potatoes be saved for seed, as they have been the soundest the last season. "They should be closer set than large ones."

A singular fact is mentioned by Mr. George Juler, of North Waltham, in a note to the editor of the Norfolk News. He says that "a person there last spring left a potato by accident in the corner of a closet in his house, which, in October, was found with seven small potatoes attached to it, and five out of the seven were spotted with the murrain."

The view which attributes the evil to a *parasitic fungus* has also its advocates in Great Britain, and some of these are among the ablest men of science. The following, from the Rev. Mr. Berkley, pronounced by Professors Lindley, Playfair, and Kane as the ablest naturalist in his knowledge of the habits of the fungi in the Kingdom, presents this view of the cause as first stated there. After having said that he could not hear of it as prevailing in his neighborhood, he writes: "I have this morning received from Dr. Montague, of Paris, some leaves affected with the mildew, together with an admirable analysis of it, and it proves to be a minute mould of the genus *Botrytis*, very greatly resembling that which is so common on the 'shepherd's purse,' especially on those plants which are attacked by the white *uredo*. It is also allied to *Botrytis destructor*, which is occasionally a perfect pest among the different species of Allium. I have seen whole beds of shallots entirely destroyed by it, and it is occasionally very prejudicial to onions. The parasite of the potato does not appear to have been before observed by systematists, and differs from those of the same genus, in several respects, which have long been known as attacking the leaves of various plants. Dr. Montague proposes to call it *Botrytis infestans*," &c. "He does not undertake to say that the spots on the tuber are owing to the ravages of the Botrytis, or whether the two causes of disease co-exist. The *primary* cause is doubtless the continued wet, combined with certain peculiarities of the soil. It may be observed, that the dry rot in potatoes, so ably described by Martius, arose from the attack of a fungus of a very different structure from that by which the leaves and stems are attacked in the present instance."

Again: The next week the same gentleman writes, in the Gardener's Chronicle of September 6, announcing the appearance of the disease, and says: "I do not find that the tubers are at present affected, but the haulm is decaying very rapidly, and in every case the blighted spots are covered with *Botrytis infestans*, (Mont.") He then states that the mould sent to him by Professor Lindley is identical with that on leaves, and the same kind as that he had received from Paris. He adds: "On making a very fine vertical section through the less diseased portions of the tubers, I find incipient plants of the mould in the more healthy cells; for, in general, the brown spots do not at first consist entirely of decayed cells, but still retain many in a tolerably healthy state. At a later period, probably all the cells would be more or less altered. Those which are uncolored exhibit their usual appearance; but the walls of the diseased cells are thickened, and have a granulated appearance. Both in the colored and discolored cells the grains of fecula remain unaltered, and are as sensible to the effect of iodine as ever. It is probable, therefore, that, at least in an early stage of the disease, the tubers would yield as good starch as those which are sound. There is not the slightest appearance of any processes upon the grains of fecula, as in the disease so admirably illustrated by Martius. It is the cellular tissue alone which seems to be affected. The cells immediately beneath the cuticle, especially where there is a depressed spot externally, are often affected with the mycellium to such a degree that the pure white of the mycellium predominates, and the brown tint in a great measure vanishes. Even in this case I find the grains of the fecula healthy and abundant. It appears, then, that the decay of the tuber is produced by the same cause which affects the leaves, to wit: by the growth of a mould, the development of which has been promoted by the excessive wet. The parasite does not appear to have been observed before; but there is little doubt that it will now be found to be more or less prevalent in damp and ill drained spots, in the driest years." Mr. Berkley again writes to Professor Lindley, in the Chronicle of September 20—"I have received from Dr. Montague specimens of a very curious parasite, which occurs in the intercellular passages of potatoes during the process of germination, and just after it has been completed. It was discovered in the course of some experiments made by Dr. Rayer, chief physician of the Hospital de la Charité, at Paris, who has been paying great attention to the disease which now infects potatoes. Amongst other points he finds, that, though the grains of fecula which are found in the cells of diseased potatoes are not injured, they gradually diminish in number, as in the germinating sets, till in some cases all are completely absorbed." "Dr. Montague considers the parasite above mentioned to belong to a new genus, allied to *lepedonium* and *asterophora*. He has given the little mould the name of *artotrogus hydrosporus*." Mr. Berkley still further adds: "In every case I find the *Botrytis infestans* preceding the work of destruction. It appears that while the leaves are yet green or yellowish green, the parts attacked soon become brown and withered. The appearances shown convince me that the spots on the tubers arise from the attack of the mould, and that mould is not an after organization. The most form distinct concentric circles, disposed in one or sometimes two systems, exactly as in *Oidium fructigenum*, as figured by Ehrenberg in his *Mycetogenesis*, and as may be seen almost every autumn on fallen pears and apples. In re examining specimens in which there was no external appearance of mould, I found that the spawn was very evident

in the diseased cells; but, as I before observed, the grains of starch were sound and unaffected. Some of the cells contained little cubical colorless or brownish crystals, which I had not previously met with. If the infected tubers are shut up for a day in a tin box, the mould will appear externally in little white patches, and soon fructifies."

Another writer, at a later date, also advocates the fungus theory partially, and says: "The cold and wet during the last summer have no doubt been the principal agents in fostering the murrain, rendering the potatoes predisposed to generate the fungi which now infect them, and which are probably of spontaneous growth; more attributable to the condition of the potato being favorable to their growth, than the fungi being the primary cause of all the mischief. On opening many potatoes which presented no outward appearance of being affected, I found many wherein decay had already extended about a quarter of an inch below the surface without breaking through the skin, leading me to suppose that, although the fungi increase the malady to a fearful extent, they are in the first instance caused by the unhealthy state of the potatoes, consequent upon atmospheric influence and improper cultivation. On examination, I have also found some bladder like spots on a few potatoes, which, when broken, contained innumerable fungi, tending rather to confirm me in my statement of spontaneous production." Professors Lindley, Playfair, and Kane, as the commission appointed to examine and report upon the condition of the potato crop in Ireland, observe respecting the fungus theory: "It is a very general opinion, and one entertained by men whose extensive knowledge entitles it to respect, that parasitical fungi, similar in their nature to those which produce mildew and dry rot, are the real cause of the malady," &c. They then go on to describe the conditions under which it is supposed the fungus appears, and which it is unnecessary to repeat, as the whole report may be seen in the appendix No. 6. But, say they, "that the spawn of fungi is present in large quantities in diseased potatoes, is undoubted. The evidence of the best microscopical observers would be with us conclusive on this point, even if we had not verified the fact by personal examination. We also regard it as well ascertained that these parasites spread rapidly in damp and warm situations, producing infinite mischief under such circumstances, and that their advance is only to be successfully resisted by dryness. But it does not appear to us that their being the original cause of the disease has been well established. If it were so, it is difficult to conceive why fields of potatoes placed very near to each other should be differently affected, or why certain varieties of this plant should be much more injured than others: the Irish apple potato, for example, which appears to have suffered much more extensively than any other. We are also unable to reconcile with the theory of the disease being caused by parasitical fungi, the remarkable fact that, in its present form, it is certainly of modern origin. That it may have always existed is possible, though of this we have no proof; but at least there can be no doubt that it has only manifested itself to any considerable degree within the last few years. We cannot suppose the *botrytis*, which observers find to be the kind of fungus that attacks the potatoes, to be of recent origin or creation. We must assume it to be co-existent with the potato itself, and therefore we must conclude that some recent causes have come into operation favorable to its increase to the present alarming degree."

In some of the numerous works which have been called from the press by the potato disease the fungus theory is adopted, and in others it is dis-

puted. Mr. Buckman says that "the fungi resemble those which produce smut in barley." He finds their seeds in great numbers on the sides of the cells. He calls it *uredo tuberosum*. He regards it, however, not as the cause, but the *effect*, attributable to the peculiar season.

Mr. G. Phillips, another writer on the subject, says that he is unable to find fungi. He imputes the evil to too much moisture, the effect of long continued rains—stimulating the plant beyond its ability, and then overpowering it.

Such are the statements of different individuals distinguished for science and habits of observation, in Great Britain, respecting the *cause* of the evil and its *appearance*.

Before we pass on to the *remedies* that have been suggested, we may as well glance at the opinions held on the continent upon the same subject. Professor Morren, of Belgium, where the disease was very destructive, broached there the fungus theory. His views may be gathered from a statement which we find translated from him in one of the public journals. It says: "Mr. Morren, after stating that the evil had prevailed in Belgium for several years, though to a far less alarming degree than at present, proceeds: 'The real cause of the evil is a fungus or sort of mushroom, which the learned will classify under the genus *botrydis*, but which agriculturists, without further specification, will call a spot, a blemish, or blotches. * * * * * This mushroom is of extreme tenuity, but it breeds amazingly and reproduces itself by thousands. Its stems are formed of little straight, hollow threads, which bear on their summits one or more branches, always divided into two, and at the end of these branches reproductive bodies are found, which have the form of eggs, but which are scarcely the one-hundredth part of millimetre in size. It will be said that this is a very small body to do so much mischief, but I answer that the itch is not a disease less to be feared because the *acare* which produces it can be seen only by the aid of the microscope. After the formation of the yellow spot, and the development of the botrydis on the leaf of the potato, the stalk receives the deleterious influence. Here and there its epidermis turns brown, blackens, and, following with the microscope the phases of the evil, you perceive that it is by the rind that the stalk is attacked. The morbid agent carries its action from the rind on the epidermis; and, although this last does not always disclose mushrooms, it is not the less for that struck with death. The infection soon descends into the tubercle itself. If the disease follows its course, the tubercle mortifies forthwith. A potato is not a root, but a real branch, whence it follows that a tubercle contains a marrow, which is the eatable part to be preferred, and a separate rind; between the marrow and the rind there is a zone of vessels which represent wood. This construction will be apparent to any one who chooses to cut a thin slice of potato and place it between his eye and the daylight. The infection attacks that part which receives the sap on its descent. By following the progress of the evil upon a great number of tainted tubercles, I have been able to see how the evil, by one continuous progress, at length reaches the heart itself of the potato and corrupts the vegetable entirely. The skin of the diseased potato comes off easily; the flesh no longer cracks under the knife; a flatulent liquid drips from the potato; a musty, and presently an animal smell, analogous to the smell of mushrooms recently cut, manifests itself, and occasions considerable nausea. * * * * * The evil being traced to its source, the cultivator must direct all his attention to the destruction

of the fungus or mushroom, for it is unfortunately but too true that all the parasites of this genus once introduced into a country remain there and propagate. This year the epidemic has been general; the germs exist every where; millions upon millions of propagules, if their number is not diminished this year, will next year be attacking the plants, and then it will be more difficult to eradicate the scourge.' "

The French naturalists, however, do not generally agree with Professor Morren. The correspondent of the National Intelligencer states that, "at a late meeting of the Academy of Sciences, M. Decaisne, of the Garden of Plants, who had examined, in every way, a number of diseased potatoes from Holland and the neighborhood of Paris, disputed the opinion of the Belgian Professor Morren concerning the cause or proximate agent of the malady. He seemed to convince the Academy that the parasite mushroom of the Professor is one of the *products*, and not the *cause* of the evil. It was stated that the human epidemic which ravaged Germany in 1816 and 1817, was chiefly owing to the habitual consumption of diseased potatoes. In the *Comptes Rendus*, Nos. 13 to 16, 1845, M. Payen gives the result of his chemical investigation: "The dry matter, which is all except water, is lessened 12 per cent. The diseased part is twice as heavy as the healthy part. This he attributes to a parasite. The loss of starch amounts to 20 per cent. There is also azotised matter of the same composition as the fungi. Messrs. Girardin and Bidard, however, deny that these are parasites. They say that there are none indicated except such as are found in all cases of fermentation. They regard the disease, therefore, as the result of simple fermentation, induced by the unfavorable season. M. Durand also attributes it to the atmospheric causes, favored by local circumstances. M. Gerard adverted to the fact that the disease attacked the potatoes between the 10th and 15th of August. He is opposed to the idea that either animal or vegetable parasitism is connected with it as a cause, and he ascribes the disease to the presence of a brown matter which seems to glue the starch grains together and to prevent their separation. He attributes its presence to unfavorable atmospheric causes, which caused the nutritive fluids to stagnate, and thus produced an alteration which ended in decay."

The *extent* of the disease in the north of France, according to a Rouen journal, was one-fifth of the whole crop. It is supposed, it is said, that the cold nights and rain have caused it. The nature of the soil or kind of seed did not seem to alter the case. In French Flanders and Belgium, also, the evil was greatly felt. Accounts from Stenay, on the Meuse, state that it has extended to that country. In Prussia, also, a German professor there writes, says the Gardener's Chronicle—"As regards the potato epidemic, it is only partial here, and confined to the early kinds in heavy clay lands. In Bavaria mention of it is made, and it is said to be distinguished from the disease in 1842, by the rapidity with which the infected potatoes run into a state of putrefaction, by the *absence of any evident fungus*, *spawn*, or *mycelium*, and by the obliteration of the membrane of the cells before any diseased action is visible in the starch grains. I am," says he, "perfectly satisfied that it is the *extraordinary season*, combined with the negligence of our cultivators, and their bad treatment of the plant, that has caused it to be visited with this calamity. I cannot believe that any parasitical fungus has produced any such mischief."

"A letter from Berlin," says the Gardener's Chronicle, "states that, by means of the microscope, the cause of the malady prevalent in the potato

has been discovered to be *insects* of an exceedingly small species. They create cavities in the tubercle, and soon produce putrefaction. Lithographic drawings have been made of the diseased parts of the vegetable, and of the insects alluded to, and copies have been sent to the principal agriculturists."

The disease is likewise described as spreading more and more in Denmark and Sweden. The Cologne Gazette states that nearly the whole growth of potatoes in the Rhenish province is lost. In Holland, according to the official report of the agricultural society of Groningen, the malady is to be ascribed to the heavy rains of 1844, in the summer, and to the weather which prevailed just at the time the tubercle seeds were formed, and partly to the carelessness of agriculturists in keeping the potatoes intended for planting perfectly dry. It is thought, too, that the excessive cold of last March proved very injurious. As more direct causes, are stated—1st, the too rapid growth of plants this year; 2d, the excessive heat which prevailed in the early part of the summer of the present year—being, on the 13th of June, 87° Fah., on the 3d of July, 87½°, and on the 7th of the same month, 91½°—3d, the rain which fell at intervals, and which subjected the plants, as it were, to the action of warm water; 4th, the cold and moist temperature which succeeded from the 15th of July to the end of August; 5th, the existence in several places of an extraordinary fog, which, in several places, emitted a disagreeable odor. They attribute much to this miasma. In the province of Groningen it was clearly ascertained that the infection proceeded from the leaves and the stalk to the root, and that it was displayed by small stains, and by the existence of a species of mushroom, placed by some writers under the head *Fusisporum solani*. No traces of these parasites were discovered in the stalks or the tubercles; a fact considered as proof that the disease was first propagated from the leaves, and consequently that it differs essentially from those murrains which originate in the roots. We maintain, say the committee, "that this disease has probably existed before, more or less; but that it is one which hitherto has not been described by naturalists." The whole report may be found in appendix No. 6.

Prof. Liebig's opinion of the disease is as follows: "The researches I have undertaken upon the sound and diseased potatoes of the present year, have disclosed to me the remarkable fact that they contain in the sap a considerable quantity of vegetable casein, (cheese,) precipitable by acids. This constituent I did not observe in my previous researches. It would appear that from atmospheric causes, a part of the vegetable albumen which prevails in the potato has become converted into vegetable casein. The instability of this last substance is well known; hence the facility with which the potato containing it undergoes putrefaction."

At the Academy of Sciences, Paris, 1845, November 17, M. Boussingault communicated an extract of a letter from Joachim Acosta, of Bogota, relative to the potato disease. It appears from this letter that the malady is very common on the table land of Bogota; that it is destructive in wet seasons, or even every year in damp spots. M. Acosta does not doubt that the malady has always been known there, since it excites no alarm among the Indians, who live principally upon potatoes. M. Boussingault properly remarks that in these countries, where cultivation continues without intermission during the year, and where the tubers are consumed without the necessity of storing them, there is no fear, as with us, of a bad harvest, be-

cause it may be replaced immediately by a good one. With us, where the culture is annual, and the product must be preserved through the winter, it is natural that we should be concerned in a malady which may destroy the resources of a whole year."

The *remedies* suggested for the cure or prevention of the evil, both in Great Britain and on the continent, embrace the *two* great objects of the *present* and *future* crops. The attention was of course first directed as soon as possible to *prevent the spread of the disease* any further, and to save those which still remained sound in the soil or after they were dug. After the disease had advanced, and all that could be expected had been suggested in the first and subsequent stages of the disease, as related to the then present crop, the inquiry naturally became one of yet deeper interest, whether the same alarming decrease of the potato crop was to be expected the next season, and to provide means, as far as possible, to ward off such a calamity. It is not always possible to keep these distinct, as, when the disease advanced, the two points were often naturally mentioned in connexion.

On the first appearance of the disease, in the opinion of the editor of the Gardener's Chronicle, there was no cure. He says: "Should we have fine weather, the disease will disappear; should rain and cold continue, it will spread." This of course is in accordance with the view he had taken of its cause. He advises to let the potatoes all rot in the cold ground, and says that perhaps *mowing the haulm* may be useful. As a remedy for their unripeness, he suggests "putting them in heaps, with alternate layers of dry earth and tubers." In his next number he recommends "*kiln-drying*" as a mode to be adopted for driving off the moisture. The next article on the subject says: "It will not do to pit potatoes in heaps, covered with straw and dry earth, as the tuber infected with mould will give the disease to the others. If pitted, they must be separated each from the other by earth." The kiln-drying is again recommended, (September 20.) and the process resorted to by Dr. Valdez, of Brussels, is quoted. He heated an oven to nearly 180° Fahrenheit, in which he placed diseased potatoes, both whole and cut. After a few minutes, a copious blackish matter oozed out of the potatoes, and they emitted a nauseous fetid smell. "This matter came out, and, when the potatoes were not too much diseased, they became white again, and nothing remained of the rot except a slight brownish layer adhering to the skin, and easily removed by peeling. This layer is compact, and will permit nothing to pass through it into the interior; it loses, moreover, all power of injuring the sound parts that remain." When the potatoes are quite dry, which Dr. Valdez found to be from eighteen to twenty-two minutes, they may be removed from the oven.

The suggestion was early made of arresting the decay in the ground by the use of chloride of lime and salt. Professor Morren also recommended salt by the use of a steep composed of 54 pounds of lime, $\frac{1}{4}$ pound of sulphate of copper, 7 pounds of salt, and about 25 gallons of water. Others, too, resorted to steeps variously compounded, but embracing one or more of the articles above named. Sulphur is also mentioned as useful on the tops and tubers. In some cases, salt is considered to have been anything but preventive in its effects. The fact that the disease was so great in the islands of Jersey, Guernsey, and Wight, where it first appeared, as well as along the seacoast, where it spread, was urged as a decisive proof that salt

was not an effectual preventive. Instances on both sides of the question are cited.

Professor Liebig recommends "the cutting of the diseased potato into slices of about a quarter of an inch thick, and immersing them in water containing from two to three per cent. of sulphuric acid. After 24 hours, draw off the acid liquor, and wash away the remains of it by steeping the cut potatoes in water. Then let them be dried. The pieces are said to be white and of little weight, and can be ground to flour and baked into bread along with the flour of wheat."

The following suggestions are also made as to means of prevention: "In the Dusseldorf Gazette it is stated that a farmer, living on one of the estates of the Duke de Aremburg, near Dusseldorf, has discovered a mode to prevent the rotting of potatoes, and even of curing it where it has already commenced. The method is very simple: it consists in merely harrowing deeply the earth in which the tubers are planted, so as to produce an evaporation, which will diminish the fermentation caused by humidity; and it is added, that the plan has proved to be completely successful. Let it be tried wherever it is not now too late. In our publication of Monday, we quoted from the Moniteur a proposition for preserving from decay potatoes partially tainted, by a sort of semi-baking in an oven heated to 64 or 65 degrees of Reaumur, (about 180 of Fahrenheit,) and the plan like that of converting them into facula or arrowroot may answer very well on a small scale. We would recommend slicing, stringing, and hanging them in kitchens and outhouses, as apples are managed in America, as a means of saving part of the crop, in addition to the two first described methods."—*London Freeman's Journal.*

Steaming potatoes, and then drying them, has also been stated to be successful by a correspondent of the Mark Lane Express. The writer says, that "on opening a pit containing 100 sacks of potatoes, nine-tenths were found to be diseased." To his surprise, "on steaming them the offensive matter was removed, and the remainder was perfect and fit for use."

An experiment by Major Beamish is also mentioned in the same journal, in which, by boiling the diseased tuber in two waters, he rendered it available for human food.

One of the earliest recommendations respecting the use of the diseased tubers, was that of *converting them at once into starch and flour.* This brought up the question, whether they were poisonous; and experiments were tried in England, and on various parts of the continent, to determine this question. The conclusion seemed to be decisive, that, as a general thing, they may be used with safety, provided suitable precautions be adopted. Professor Lindley speaks of a fine potato flour received from some of his correspondents, and says: "Professor Henslow found that while a half bushel of sound potatoes yielded 4 pounds 10 ounces of flour, the same quantity of diseased ones furnished 3 pounds 10 ounces." Numerous methods of preparing flour and starch, agreeing in the main, are found in the agricultural journals. We have extracted several of these in our appendix No. 6.

A curious experiment is named in a French paper as having been tried by M. Bonjean, of Chambery, who lived for three consecutive days on bad potatoes, which had been thrown aside as refuse. He said, that, to determine the question of danger, he had none of the diseased portions cut away. In three days he ate 8 lbs. in butter, in soup, or simply cooked in water,

without any inconvenience, except a slight indigestion. He also drank in the morning, fasting, a glass (about 8 ounces) of water in which about 5 pounds of putrid tubers had been boiled; it was of a yellowish brown color, turbid and thick, but not viscous; of a slightly disagreeable smell and nauseous taste, leaving a bitterness which remained on the palate for an hour. He says he found "no other symptoms of indigestion from this liquid except a disagreeable heat oppressing the chest for about two hours." Whatever may be thought of M. Bonjean's taste, his philanthropy, at least, is deserving of praise.

In a statement of a method of use, made by M. Croker, at a meeting of the Cork Agricultural Society—which is very valuable, as it may be adopted in any family—he says:

One weight (20 lbs.) of sound white potatoes will produce of dry farina, or flour fit for use -	3 lbs.	9 oz.	0 drachms.
One weight (20 lbs.) of unsound, and diseased part cut off - - - - -	3	1	0
One weight (20 lbs.) of unsound minions -	3	1	0
One weight (20 lbs.) of unsound and paired -	3	0	0
One weight (20 lbs.) of unsound potatoes, none cut off - - - - - -	3	6	0

"The farina or flour from these will be dry and fit for use." He also states that diseased potatoes make as good starch as the soundest. "The bad parts need not be cut off; they must be well washed to prevent the earthy particles from mixing with the flour."

The suggestions of the Irish commission, in their report, as well as those of agricultural clubs, chemists, &c., respecting the methods of using the crops, are highly valuable, and will repay the time spent in their perusal. The Hadleigh Farmers' Club, in their statement, give a number of simple directions, which propably embrace the greatest number of particulars in the shortest compass of any of the public documents we have seen.

It is a point of much interest and discussion, "How shall the next crop be prepared?" It does not seem to be positively decided that diseased tubers might not be used, but it is recommended that, as far as possible, this should be avoided. Mr. Berkley states that the presence of fungus would not necessarily vitiate the powers of production. "He states," say Professors Lindley, Playfair, and Kane, "that though there would certainly be some risk in raising a diseased progeny from a diseased stock, yet the growth of fungi so evidently depends on atmospheric condition that it does not follow that because germs are present they should be developed." The use of home grown potatoes, that have remained sound during the winter, is admitted to be safe; but it is recommended that autumn planting should be resorted to instead of spring planting, and that the potatoes should be planted as far as possible from where the diseased ones are raised. The use of certain substances, as lime, salt, &c., is also suggested as likely to prove of advantage. The procuring of new varieties, also, occupies considerable attention, and a number of papers containing valuable suggestions on this and kindred subjects will also be found in our appendix No. 6. Mr. Patillo and Professor Lindley both recommend as best for seed potatoes those which are *not* the best for table use. Mr. Tison states, in reference to seed potatoes, that he plants an early crop, and, when fit, he removes them, setting in their place small waste potatoes saved from last season. When about half grown, and the tops are still luxuriant, &c., he takes them up

and spreads them over the land, allowing them to lie until winter—turning them; and they always yield more and better potatoes.

In reference to autumn planting, Professor Lindley recommends to look for the *early* varieties, and also to keep in mind the important facts—"1. The eyes at the top of the potato are the youngest, and vegetate first; from them the crop obtained will be a fortnight earlier than from the lower end. 2. When the potato is not cut, and the top eyes are allowed to proceed in their own growth, they push slowly, if at all. 3. If the top sprout be removed, the other eyes will begin to grow with greater vigor. 4. The top sprouts may be removed when they begin to show roots, and planted out for the earliest crop, and the rest of the tuber be allowed to push the other eyes, &c. 5. If sets are scarce, stems may be layered; they will root and form a second crop of tubers; but this must be done early in the season, or before the first set of tubers is fully ripe, though large enough to be fit for use."

An interesting paper, in the Irish Farmers' Journal, on the productiveness of potato sets, (for which see the appendix,) gives a statement respecting the different kinds of sets, as follows:

		Produce.
No. 1.	Tops, or rose eyes	24 pounds.
2.	Bottom eyes	14½ do
3.	Strong eyes, that had sprouted	20½ do
4.	Later eyes, that had not sprouted	16 do
5.	Cut downwards, with protuberance	14 do
6.	Cut upwards, without protuberance	14 do
7.	Nipple eyes	7½ do
8.	As in No. 5	20 do
9.	As in No. 6	14 do
10.	As in No. 7	5 do
11.	Deep eyed sets	11 do
12.	Shallow-eyed sets, disposed to nipple	11½ do
13.	Deep eyed, mixed with a red potato	8 do
14.	Deep-eyed, mixed with a red potato	16 do

A writer in the Gardener's Chronicle states, that from 18 large cut potatoes, weighing 7½ pounds, last spring, he took 176 fine scoops one inch in diameter and one inch deep, which weighed 4½ pounds. An acre planted in rows, 4 feet asunder, the sets 9 inches apart, would take 14,520 sets, weighing only 3 cwt. 1 stone; with refuse, fit for food, 2 cwt. and 3 stone. Mr, Gray, of Dilston, in the Chronicle of October 25, gives an account of an experiment on the comparative produce of autumn and spring planted potatoes, the results of which he describes as being thus: "The average length of the drill rows required to fill the sack—

Of October planting, was	30 yards
Of November planting, was	32 do
Of December planting, was	32 do
Of March planting, was	41 do
Of April planting, was	45 do

Which leaves to the October planting an increase of one-third over that of April."

J. A. Dorant, of St. Albans, says, in favor of autumn planting, that it

seems to protect from the blight. He states that his crop, on being taken up, is found to be a fair average one—free from murrain or any disease; as clean and fine flavored as he ever dressed.

In a pamphlet by R. Arthur, he recommends the hybridization of potatoes, to obtain the best seed. The method is the following: "Select 6 or 12 superior healthy varieties; place one tuber of each in a warm situation, and cover it with earth. When the eyes have sprung 4 or 5 inches, take the strongest one from each tuber, with a good set to it. Put each set into a good flower pot, and cover it about four inches with peat earth and rotten dung. Bury the pots to the brim in a warm place till the stem grows six inches to a foot in height. Then turn the pot upside down, holding the stem of the potato between the two inside fingers of the left hand. Lift away the pot, and so leave the ball of mould entire. The young potatoes will be on the outside of the ball. Remove these carefully, and also the old set if it is there. Plant the set out in a rich soil, at the base of a west or south aspect wall, and water it well. Train each plant by a single stem on the wall, and give it liquid manure in dull showery weather. When the flowers appear,thin them out with scissors, and leave only one or two of the strongest. The moment they *begin* to expand, cautiously open each flower, and with small scissors or tweezers remove the fine little anthers, leaving the centre stigma. The next morning procure a full-blown potato from the field, and dust the pollen of its anthers over the stigma of the flower so prepared. Do this again the next morning. In this way hybrids or mules can be obtained between any two plants of natural affinities. Remove early any young potatoes which may be produced near the surface; and so the plant, when well grown and not producing potatoes, will produce, says Mr. Arthur, enormous seed plums, which will produce some hundred varieties of blacks, whites, reds, &c. The sorts should be labelled, &c. The plum, when ripe, is to be preserved from frost till shrivelled, &c., and then the pulp may be mixed with peat mould till sowing time."

Mr. Arthur strenuously urges that if potatoes are cut for planting, it should be in the autumn, and not in the spring. He seems to suppose that much of the evil arises from the latter practice. He says, "it may be cut at any time during its dormant repose, as it is protected during the winter." But, he says, "it is contrary to nature to dissect it at the only stage of its annual life, when we know all other plants bleed excessively if wounded." Curl and wet rot he thinks to be "produced by the effects of wet land or wet cold seasons operating on the set, and surcharging the empty bled vessels with cold unnatural sap," &c.

In another pamphlet which has been called out by the prevalent disease, the author says that he considers the great error to be in "planting the seed in a quantity of dung laid in the middle of the drill." He would place the potato in the clear soil, on the back of the half-drill formed by the return of the plough, which half-drill should be made larger than ordinary, to bring the seed as near the centre of the drill as possible, the manure having been spread evenly over the surface and dug in. He also recommends attention to the selection of varieties by adoption of some of the inferior kinds less liable to disease.

In the appendix No. 6, among other papers will be found a list of queries by Professor Johnston, to aid him in the investigation of the disease. This will be useful in directing the researches of farmers and observers another year. As reference has been made to the rot described by Von Martius, in

Germany, in 1842, we have also added some papers on this subject; one of them, translated from his report as found in the Central Blatt des Landwirthschaftlichen Vereins, of Bavaria, on purpose for this report. It was our intention to have subjoined extracts also from another work of his on potatoes, as likewise translations from the German, Belgian, and French Professors, but they have not as yet reached us. It will be seen, we think, that the disease in Europe greatly resembles that in this country; though it may be, and doubtless is, occasionally modified by the difference of circumstances in the two countries. We have not expressed any opinion as to its cause, &c., as, amid such conflicting testimony, it seems advisable to wait for more light. The great importance of the subject will form a sufficient apology for dwelling at such length upon it. Our aim has been to furnish, as well as we might, a condensed view of the progress of the disease during the past year; and this we have had to do by devoting much time and labor to collating a vast number of papers, letters, pamphlets, &c., some of the most prominent and useful of which we have placed in full in our appendices. We believe that we have not passed over any opinion of importance. This mass of materials will be more readily at command for observers another year, and perhaps may afford important aid in anticipating and arresting the progress of the disease in future. The theories may all be wrong; but the evil exists, and it will be a real benefit to our country, and the whole civilized world, if its ravages may be checked and terminated.

The American Institute, in a late session in New York, passed the following resolution:

"*Resolved*, That the alarming situation of a great part of the world at this time, in consequence of the disease called the rot in potatoes, requires the most active, prompt, and untiring exertions of all the producers of this most important production to subdue, if possible, the frightful ravages of this disease, and to prove, by successful experiment, that the country which originally produced this valuable root, one of the most sustained sources of subsistence to the population of Europe as well as our own country, can provide a remedy to prevent its extinction."

HAY.

Hay is a more important crop in New England and some of the middle States than in other parts of the United States. The vast prairies of the west, and the moderate climate of the south and southwest, allowing pasturing even during the winter months, render the cultivation of the English grasses less an object of attention in those sections of our country.

The crop of hay seems to have been very good in Maine. The Maine Farmer, speaking of it, says, July 11: "The grass crop, from present appearances, will be light; nothing near an average one. In many newly laid down fields we noticed that the ground was hardly covered with a decent mantle of green, the clover having been winter killed. The old and middle aged mowing fields, with but few exceptions, along the whole route, looked remarkably thin, and, unless the late propitious rains have given the grass a healthy and unprecedented impetus, the growth will be small, and the crop harvested not more than adequate to meet the wants of the farmers and supply the village markets." Again, July 31: "Our farmers are in the midst of this important harvest, and we are happy to state that, although

the season was at first very unfavorable for grass, and promised a scanty return, the results are very good. In this vicinity the crop is nearly as abundant as it was last season, and the quality is undoubtedly far better. For the last week the weather, owing to the frequent showers, has been rather unfavorable for getting the hay into the barn; but the benefit that has resulted to the other crops from the seasonable rains more than counterbalances this trouble." Again: "We are happy to state, that although the season was at first very unfavorable for grass, and promised a scanty return, the results are very good. In this vicinity the crop is nearly as abundant as it was the last season, and the quality is undoubtedly far better." At an earlier date the Norridgewock Press says: "Vegetation of all kinds along the Kennebeck looks extremely promising. Hay seems likely to turn out as abundant as last year." There was probably a small increase, therefore, as the crop of the previous year was a good one, of perhaps five per cent. In New Hampshire the drought was so severe as to cut off the crop to a large extent. By some the falling off is put as high as "fifty per cent." In the southeastern part of the State it is believed to have been "fifteen per cent. less." Further west, and in the central southern section of the State, it is estimated at "twenty-five per cent. less." A correspondent still higher up on the Connecticut river writes thus: "Long continued dryness had a bad effect upon the hay crop as to quantity, though the quality is considered to be unusually good. Taking both into consideration, the regular crop cannot be well estimated at more than two-thirds of an average one. The copious rains of August caused the grass to spring up with unusual vigor, and the aftermath, or second cutting, was more productive than common, and the feed in the pastures in the latter part of the summer was unusually good. Fields recently laid down to grass, and which were in good condition, suffered none, unless the land was very light and sandy; on the contrary, many new pieces of mowing yielded a very heavy crop, while such as had been in grass for three or four years yielded very scantily. Farmers are apt to let their grass remain too long—as long, indeed, as it will, in ordinary seasons, yield a barely remunerating crop; and thus they are sure to suffer when the summer is even but a little drier than common. Did a better organized and shorter system of rotation prevail, it seems probable that such a drought as that of last season would have injured the hay crop but little." The crop for the whole State (regard being had to the proportion the counties bear in the returns of the census) is believed to have been twenty-five to thirty per cent. less than in 1844.

The severe drought also affected the crop in Vermont, although, it is believed, not equally with that in New Hampshire. In the lower part of the State it fell off perhaps "ten per cent.;" in the upper it appears to have been "about the same" as in the previous year. The whole decrease was probably from five to ten per cent. Some fine crops are mentioned as having been presented for premium at the fairs, &c.; but these, as they are secured by extraordinary means, form no fair criterion as to the general crop. Five acres, in one case, yielded 372,000 pounds, or about $3\frac{1}{2}$ tons and 440 pounds to the acre. This was produced by means of top-dressing and irrigation.

Another account is as follows: "Mr. H. P. Hickock, of this place, (Burlington, Vt., Free Press) gathered in from $2\frac{1}{2}$ acres of meadow, last week, thirteen great loads of hay in good order. The hay was herdsgrass, with a sprinkling of red clover and red top; and the loads are estimated by

the hands in the field at one ton each. This field was cleared of pine stumps, and heavily manured, some 25 years ago. Since then it has invariably produced large crops, mostly of hay, and with very little manure of any description. Five tons of the best hay to the acre is something for the most fertile district of country to tell of."

The accounts of this crop in July and August, in Massachusetts, are discouraging. Thus the Massachusetts Ploughman, of July 14, says: "We had in this vicinity last week six good hay days, and much of our early hay was secured. It is now the 14th, and the weather is quite dry enough for any purpose. We shall expect no rain, but of nights and on Sundays, till haying is over. This is the week for herdsgrass, red top, Rhode Island, and the spear grasses." Later in the month, "the Greenfield Gazette reports the grass crop as light, and states that many farmers have commenced their haying; and it is believed the crops will not be more than two thirds yield." And in August it is said: "The crop of grass, however, is generally light, and will probably not much exceed the consumption."

In the northeastern part of the State it is thought that the drought lessened the crop of English hay "25 per cent." Fresh meadow hay was "10 per cent. better;" and salt hay also gave an increase. In the central, along the eastern part of the State, the deficiency is differently estimated in different towns, from "10 to 40 per cent." In the interior, "10 to 15 per cent. less;" while in the western section it probably fell off "one-quarter." A correspondent of the Boston Cultivator, writing from Berkshire county, in the early part of July, says: "The crop of grass is now very light, and should it be cut at the usual time of haying, there would probably be a falling off of one-half from last year. But the rains which have commenced falling for the last two or three days have given it a new countenance; and, should July be a wet month, there may yet be a supply." The general effect of the drought probably reduced the crop for the whole State 25 per cent.

The crop of Rhode Island is believed to have been better than in the preceding year. In Connecticut there was some decrease—probably 15 to 20 per cent.

The hay crop in New York was less than in the preceding year. Great complaint is made of the drought. Thus the agricultural report for July, in one of the public journals, says: "We have had a miserable season from the commencement. May and June were unusually dry months, and July has exceeded them all. The grass never looked worse. Clover ripened prematurely, and was cut out of season. The yield was hardly enough to pay for the labor. Timothy grass suffered less, but the crop, although secured in beautiful weather, turned out to be less than half the usual yield." We have never known the pastures to look so uninviting. The ground is apparently burnt up. Vegetation where the grass has been cut is dead. The springs are dry, and low grounds that are usually wet and swampy are as dry as the hills. Cattle show the poverty of the pastures by their appearance; and the cows fail to supply the usual quantity of milk." And the same paper, for August, says: "The rains came too late to help this indispensable crop, except on the salt meadows. The yield of the uplands is a failure; but the salt grass, which is an important article, is turning out remarkably well. The rains have fallen so seasonably, that the second cutting will, in many places, be uncommonly large. The change between July and August can hardly be realized. The fields that were a month

ago burnt up to such a degree as not to afford the promise of a spear of living grass, are now clothed in the richest green."

A Troy paper of July also states, that "the grass crop will not be more than an average one."

A paper in Buffalo gives the following statement in July, respecting the hay crop in that region: "We shall have a lighter crop than has ever before been made in this country. Thousands of acres have not yielded half a ton to the acre. It is safe to say that the crop will not yield more than one third. Farmers are devising ways and means to meet this alarming state of things. All the stock that can be possibly spared will be sold or slaughtered. Sheep will be slaughtered by the thousands, because they pay better than any other stock, and wool has been low, and dairy products higher in proportion. There will not be near as many sheep wintered the coming winter as there was last. The decrease will be a great many more than the increase this year."

In the Batavia Times, in August: "Grass, though not half the usual quantity, is excellent in quality; one ton being equal to $1\frac{1}{2}$ ton in ordinary seasons."

Complaints respecting the crop are also made in the northeastern section of the State. The accounts from other sources represent the crop in general as light. In some few cases it may have been an average, but in most cases it fell from "10 to 25 per cent.;" in some instances even "50 per cent." In Westchester and Rockland counties, it is thought to have been somewhat more. Further up the river the decrease, in some cases, is rated at "40 per cent." greater than in 1844, and northward from "25 to 50 per cent." In Ulster and Delaware counties, about the same decrease. In Otsego, Schoharie, and vicinity, it was considered "an average crop," and of "a very superior quality." Along the Mohawk valley, and northward, from "15 to 25 per cent." less. In the central portion of the State, to the east, the decline was from "20 to 25 per cent.," on account of the frosts late in the spring, and the dry weather succeeding. Towards the lake it was, perhaps, not so much decreased; while as we proceed westerly, in all the counties, there was a lessening of the crop from "20 to 25 per cent." at the north, and from "10 to 15 per cent." south and southwest. The falling off for the whole State was probably about 25 per cent.

The crop of hay in New Jersey seems, also, to have been quite light. In the western part of the State the drought was felt so severely that it is thought the decrease was from "33 to 40 per cent." In the central section of the State, also, it is said to have been very light; indeed, "about one-fourth" of the usual crop. Still lower down there was a similar decrease, as we may see from the following extract in reference to one kind of grass: "The crop of herdseed grass in Salem county, New Jersey, the present year, will fall short of that of last year at least two-thirds, occasioned by the frosts last spring, and the drought that followed during the summer. Salem county furnishes a large portion of the herdsgrass seed for market of the whole Union." The decrease for the whole State must have been from 20 to 25 per cent.

The early promise in Pennsylvania, which is among the foremost of the States in the amount of this crop, was good; but, on account of the severe drought, it fell off almost every where. In the vicinity of Philadelphia the decrease is estimated at "25 per cent." In Chester county, "one-half;" Lancaster nearly as much—"30 or 40 per cent." The crop, we are told,

was "very light" in general. "Some well informed farmers think it was not more than 50 per cent. of last year's crop; others are of opinion the difference was not so great." Our informant inclines to the latter view. In the counties of Adams and York, lying along the line of Maryland and the Susquehannah, it is judged to have been "50 per cent. less." In the east central section of the State there was "not more than half a crop." The deficiency was not so great probably in Columbia, Luzerne, and Wyoming; while in the northwestern counties, towards the centre, the falling off from the crop of 1844 is fixed as high as "30 per cent." We believe that from 25 to 30 per cent. less will not be too great an average for the whole State.

The same was no doubt the case with Delaware and Maryland. In the northeastern section the decrease is rated as high as "one-third." Virginia, with the States lying south along the Atlantic coast, raised but comparatively little hay; and hence it is not easy to get any very definite information respecting them. The drought, however, was severe, as we have already seen in the accounts of other crops. The lessening of the crop from that of 1844 in Central Virginia was great, as it is said to have been almost totally destroyed. In the northwestern part of the State, as well as on the Kanawha and its branches, the decrease is estimated at "40 per cent." According to the best judgment we can form, one third less than the crop of 1844 may be considered rather under than over the truth.

The universal account both from North and South Carolina, is at least "50 per cent. less." The Southern Planter, speaking of this section, says: "The clover crop has probably suffered most, both the crop of this spring and the last; and we regret it the more, because this great improver, owing to the low price at which the seed has been sold, has been very extensively seeded." In Georgia, likewise, the drought greatly injured the crop; and in Alabama, also; but in this latter State, probably not as much as in the former. In Tennessee, in some parts the crop fell off, and in others was improved. In Kentucky, the decrease is said to have been "15, 20, 30," and even in some sections probably "50 per cent."

The hay crop also suffered greatly in Ohio. The report of jurors from various counties, as furnished in one of the public journals, is as follows: Lake county—"Grass crop light; not more than one half, or one-third." Highland—"Very light." Meigs—Grass, "two thirds of last year's crop." Fairfield—"Very light." Guernsey—"About a half crop." Hamilton—"Hay crop smaller than usual, and inferior in quality." Butler, Warren, and Preble—"Much as in Hamilton."

The accounts otherwise obtained are similar. In the northeastern section, on the Reserve, it is judged to have fallen off "two thirds, if not more." The same was the case in the counties bordering on the Ohio river and Pennsylvania, east of the central counties. In the immediate central counties, including Delaware, Marion, and Richland, it is considered to have been from "20 to 25 per cent. better;" and the decrease was not so great as in some of the other sections; probably not more than "15 per cent.;" while in the southwest the drought caused a great falling off of the amount made. In the southwestern section of the State the crop was "20 to 50 per cent. less." It was much injured by late and heavy frosts, and a severe and protracted drought. While in the northwestern and along the lake, towards the centre, west, it is variously estimated at a decrease of from "20 to 50 per cent.," and even higher. It is evident, therefore, that there was a large falling off of the hay crop, and we believe we are within bounds

when we put it at an average of one-third less than the crop of 1844, which was a considerable gain over the crop of the preceding year. We should say that this was, if it needs any correction, too small a deduction, and perhaps the falling off should be fixed as high as 40 to 50 per cent. The Painesville Telegraph, speaking of the region near the lake, says: "They are forming clubs and sending forth men to secure the grass that grows on the prairies in great abundance, and free to all; and in the fall the cattle will be driven out to be kept through the winter, and returned again in the spring."

As early as June it is stated of the Indiana crop, in an agricultural journal, that "grass in the State will be light—the recent rains being too late to be of benefit to this crop." In July the prospect was better. Thus, the Indiana Farmer says: "The grass has thickened up since the copious rains, and there will be a fair crop. There is enough old hay in the country to afford very nearly a supply for the year, even if the present crop wholly failed."

Other notices are like the following: "Peru, in Miami county.—Grass is almost an entire failure in this county, in consequence of the drought and cold." "Wabash county.—The crop of grass was bad generally—not, perhaps, more than half the ordinary crop; the dry weather in May and June nearly destroyed it."—*Indiana Farmer.*

A correspondent of the Farmers' Cabinet, from Richmond, in Indiana, describes the crop thus: "Grass, owing to the drought, is mostly light, though better than the farmers had anticipated." The Indianapolis Sentinel also speaks of the grass as about almost totally to fail. The almost universal estimate we obtain from all parts of the State by other sources is, that there was a great falling off—50 per cent. from the crop of 1844. In the central section, towards the west and northwest, it may have been somewhat better; perhaps not more than 30 per cent. less.

Illinois, with her extensive prairies, cultivates but little hay; and Missouri still less. In the section of the State west of the Illinois, to the Mississippi river, or the central western, it was better by 20 per cent. The heavy rains of last year (1844) greatly injured it there. In other parts it fell off from 10 to 20 per cent. In Michigan, in general, it fell off. In the eastern central section it is put as low as "three-quarters less." Southeast, and along the southern border, the decrease is thought not to have been so great; and the editor of the Michigan Farmer estimates the decrease from the crop of 1844 at "10 per cent. less." Probably, for the whole State, the falling off could not have been less than 15 or 20 per cent.

In Iowa and Wisconsin there appears to have been a general increase. Many persons who settle in those sections have been accustomed to this crop, and therefore it receives considerable attention. If we should reckon the hay made from the wild prairies, they would each, both Iowa and Wisconsin, exceed 100,000 tons. The whole crop of hay, therefore, for the United States, is estimated at 14,065,000 tons.

We have met with a number of interesting articles connected with the hay crop, especially relating to the *time of cutting*, *quantity of seed to be used*, *modes of cultivating*, *and preserving it*, which may be useful and interesting; and as such, we shall here make allusion to them, either by full quotations or in substance.

The Michigan Farmer gives the following as a good method for preventing must or mow-burn in hay: "Take a number of smooth poles and lay

the butt ends outside, so that they may be easily pulled out; let the mow or stack settle for a few days, then pull them out; this will leave a passage for the air into the hay, that will insure it against must or mow-burn for some distance around the holes."

A correspondent of the Prairie Farmer says: "People differ as to the quantity of clean timothy seed to sow on the acre. Some say half a gallon; and one man told me to sow half a bushel to the acre. I believe, from twelve years' experience, that, on our rich prairies, from four to six quarts will be sufficient; and if the ground is well set, do not let the grass get too ripe before cutting, as it will scatter seed and soon get the ground so that it will bind out, as it is called."

As regards the time for cutting hay, we quote as follows, from the Boston Cultivator: "With regard to the best time for cutting herdsgrass for hay, even practical men are divided in opinion. In a late conversation with Mr. Isaac Reeves, the proprietor of the large peach orchards in Delaware, to whom every practical man looks up with deference and the highest respect, he observed: 'I will take an old piece of herdsgrass, that at present yields less than half a ton of hay per acre, and at the end of five years, without breaking up, fresh seeding, or manuring in any way whatever, I will raise the crop to two and a half tons per acre. This I will do by merely permitting the crop to stand until the seed will just vegetate before cutting. By mowing the crop sooner than that, the roots bleed and die out; and that is the reason why a second crop does not spring up until a long time after. I once purchased the fifth part of the crop of timothy on one of the islands in the Delaware, with the intention of cutting the grass on my lot at the same time the other four purchasers cut theirs; but I was called from home, and it was not cut until the seeds would vegetate. I thought my hay was spoiled, but it was preferred to all others for horse feed; and behold! the next year my lot of land yielded double the crop of the others, and at the end of five years it had increased to two and a half tons per acre; having overgrown all other grasses—a uniform crop, five feet in height, and preferred before all others at the market. Since then I have never cut timothy until the seeds would just vegetate.' Mr. Phinney considers early cut hay the best for dairy stock; for oxen and horses he prefers to let it stand longer; the object in the first case being milk—in the last, flesh or strength. But then comes the grand consideration: the renovation of the crop by preventing the bleeding of the roots; a new idea. And would our friends examine the subject, and give us the result for the columns of the Cultivator?"

A method of top-dressing grain and grass crops is used in England, which is there called *Gurneyism*, from the inventor and introducer. It consists of covering grass land with straw, &c., and allowing this covering to lie till the grass springs through it (which it does with astonishing rapidity) to the desired length, and then raking it off to allow the beasts to reach the pasture. This is then applied to another piece, and then removed and applied again as long as the straw and covering will answer to be applied conveniently. The following is the account as given from English papers by the American Farmer: "*Covering grain and grass crops with straw.*—The Hon. G. Gurney, of Woodleigh, Cornwall, England, has been successfully experimenting with straw, rushes, and brushwood as a top dressing for grain and grass crops. He applies a ton and a quarter of straw to the statute acre, by spreading it evenly over the crop while growing, any time between the months of April and October; and when an early crop of

grass may be desirable, he spreads the straw in the latter part of February. Thus far his experiments have been tried upon wheat, vetches, meadow-grass, and clover lea; but there can be no doubt it would prove equally beneficial if applied to any other of the families of small grain and grasses. Mr. Gurney, in reply to a letter of inquiry upon the subject, remarks, that the instances of benefit are numerous, and that there is not one upon record where it has failed, except in cases where too great a quantity of covering has been applied, or, which is by far the more general, where too little has been applied." At a meeting of the East Cornwall Experimental Club, Mr. Gurney made the following remarks: "About seven weeks since I covered half a field of three acres of grass in this manner, and about a fortnight since, when examined, the increase was found to be at the rate of 5,000 pounds per acre over the other part of the field. At the same time, the straw was raked off and laid in rows about twelve feet apart on the field; 115 sheep were then put into the field with a view to eat it down as quickly as possible; and after they had been there about a week, they were succeeded by 26 bullocks, to eat off the long grass which the sheep had left. The field was eaten as bare as possible. The same straw was now thrown again over the same portion of the field from which it had been raked; and on inspection this morning, I found the action going on under it as powerfully as before." Mr. Gurney thought that the sheep, on the first raking off of the straw, were not so fond of the grass as they were of that uncovered; but after twenty-four hours' exposure to the sun and air, he thought they rather preferred it. He had now forty acres under operation, and he had grass where his neighbors had none. The editor of the American Farmer says, in reference to this mode, "Mr. Gurney's practice is to rake off the straw, and to feed the grass to his sheep once a fortnight, or once in three weeks. This raking off and reapplication of the straw does not appear to us to be essential to the success of the operation. What its *rationale* is, has not as yet been settled in England, nor in Russia, where experiments are being carried on; but in the absence of such settlement, with regard to the action of this straw dressing there are various facts, besides those adduced by Mr. Gurney, going to establish its efficiency in the promotion of the growth of such grain and grass plants as it has been applied to; and with those facts to encourage experiments, it would be turning a deaf ear to the voice of experience in our country, were not our agriculturists to profit by the experience of Europe. In the south, especially, where the artificial grasses are difficult of substantial culture, we doubt not that such dressings would be found of singular utility. Where straw may be found to be scarce, we should not hesitate a moment in substituting for it leaves and pine shatters from the forests. These, fortunately, can be obtained in almost all situations with us, and we doubt not would prove, on trial, eminently serviceable."—(See appendix No. 7.)

Again: "*Top dressing for grass lands.*—A writer in the Gardener's Chronicle lays it down as the result of his experience, first, that the proper time to top dress lands is in the fall; and, second, that the stock should not be permitted to run late thereon in the fall. In support of the first of these propositions, he maintains that, the temperature of the atmosphere and soil being cold in winter, the dung affords protection to the tender roots of the plants, and that whatever particles of fertility which may exist in the manure are in winter washed down into the soil, and lose but little of their virtue by evaporation, and that the drying winds and sun of summer are

more injurious to the manures than any drenching rain can be. Immediately after the atumnal application of manure, he recommends that the meadows should be thoroughly harrowed. A most wise recommendation is this; one that will greatly encourage the economy of the manure."

In the Mark Lane Express, of July 21, there is an account of salting in grass and hay in wet seasons, which is stated to be very useful. Mouldy hay put together with salt, from 8 to 25 pounds per ton, was better relished by cattle, and did more good, than sound hay stacked without salt. In some instances hay stacked damp with salt, so that it came out almost a paste from the rick, when opened, was devoured with avidity by the cattle. "In Germany, grass fresh cut is packed in with one pound of salt to the cwt., and it is said that it goes much further than the same quantity of grass made into hay. A method recommended as better is to stack the green grass or clover in layers, with straw and old dry hay, sprinkling salt on each green layer. The juices drawn from the grass by the salt will be absorbed by the straw or old hay, and not only the damp hay or grass will be made more nutritive, but the straw itself may thus be brought towards the state of the green stalk by the salt which it absorbs, and by which it is gradually softened, and thus made soluble and digestible. The proportion, though various, according to the dampness of the grass, will be about in this ratio: Good upland grass, cut in dry weather, contains about two-thirds of its weight of water, or two tons in three, and one ton of straw will absorb three tons of water; but as it is not wanted wet, we may allow four tons to one ton of straw; and if the grass, by aid of the salt, gives out half of its juice, we shall then have the whole soft and damp, without being disposed to drop or leak. If old hay is used in place of straw, one-third or one-half may be enough, as this absorbs less. For meadow grass or green fodder, cut damp, the straw or old hay may be increased in proportion. If the hay is partly dried, none perhaps may be needed. The best proportion of salt must be decided by trial. One pound per cwt. may be too little for fresh grass. Two pounds per cwt., or about one-half bushel to the ton, is thought to be not more than the cattle would relish, and which is more likely to preserve the whole in a sweet and digestible state. For half-dried hay one pound per cwt. may be enough. Bran is said to be a good substitute for straw or old hay. The only difficulty would be its liability to ferment and heat."

In the New York Farmer and Mechanic we find an article on the *science of mowing*, and as the rules given are simple and practical, we give them as Mr. Pitkin, by whom they are communicated to that journal, somewhat quaintly states them. He says: "It was my good fortune (for so I regard it) to have had a few years' experience in early life as a practical farmer; and as I advanced from boyhood, I remember, among other things, my first efforts and ultimate success in the science of mowing. For a time I had much difficulty in keeping my scythe sharp. This, however, I found to be indispensable. No man can approach any thing like an easy or good mower without it. I had become a good mower, when I fell in company with not only a good mower, but a scientific one; and after the second or third day, finding that I could not keep up with him without doing myself an injury, and painful as it was for me to acknowledge it, (for I was ambitious,) yet I was compelled to call my friend to a stand in the midst of my swath. I said, 'Mr. Picket, (for that was his name,) if you know any thing which you can communicate to me of the skill of mowing,

I beg of you to do so, for I am exhausted, and I may as well confess at once that I cannot keep up with you.' He stopped, came back, took my scythe, and explained to me the main governing principles. I adopted them, and in less than one hour I could keep up with him with perfect ease. Indeed, I had at least 20 per cent. more of physical strength than he had. It was science alone that enabled him to lead me to this extreme. During the following summer I came in contact with about a dozen good mowers, and I may say some three or four of them professedly *fast* mowers. I adhered strictly to the science I had learned the preceding summer. My professor not being present, I could lead the field with great ease; but I kept the secret to myself. And now for the art: I will try to describe it. 1st. The scythe should hang natural and easy, and, as I have said before, it should be kept in first-rate order. 2d. As you approach the standing grass let the heel of the scythe move to the very point of commencement, and let it stop the instant it has done its work. Thus there is nothing lost by a backward or forward swing. If the grass stands up so as to admit of moving on, measure with the eye the utmost capacity forward of your scythe; take a quick, easy gait, moving your right foot well up towards the standing grass, and your body with it, though leaning back by bending the knees a little forward, so as to bring your whole weight to bear upon the scythe without twisting the body from right to left, as many do; thus giving ease to each clip, and ability to repeat in an advanced position without fatigue.

"Note.—If you swing six inches too far back, and six inches too far in pointing out, it makes 24 inches *loss!* This applied to a scientific forward motion, will give you a great gain on ordinary mowers."

The Boston Cultivator contains a description, by Benjamin Willard, of a method of *recovering pastures*, which he says is very useful, and can be applied without manure. His account is thus presented: "This is to turn them over the last of July, or as soon after as business will permit, and sow two bushels of rye to the acre, and bush in the grass seed. I sow one bushel of plaster to the acre after the rye is up; and when it is well up I turn on sheep. In the spring, I again dress it with plaster, and give it one bushel of red-top to the acre, and keep sheep enough on it to prevent its rising till the last of May; then cattle may be put on if desired. It will last through the summer, and produce abundantly till the grass is well rooted. Pastures thus treated will look surprisingly verdant, and will last several years. Nothing suits sheep and calves better than the rye. The same course may be pursued with exhausted land or bushy pastures. I prefer to keep sheep there the first year, as they keep every spire of it close, and thus make it spread, and they manure it more equally than cattle, and do not injure the grass, in its tender state, with their feet."

In the Quarterly Journal of Agriculture of the Highland and Agricultural Society of Scotland, we find mention of two new species of clover, (which are described as follows by M. Vilmorin, in the *Bon Jardinier;*) one of which is the hybrid, and the other the elegant. The elegant clover was for a time considered identical with the hybrid, which is cultivated in Sweden; but when growing together, the differences are stated to be striking. "The latter is larger in all its parts than the former, and the color of its flowers is a brighter rose, shaded with white in the centre, while the elegant trefoil has rather dull reddish rose-colored blossoms alike in every part of the flower-head. The appearance of the herbage is different; the hybrid clover has

dark and bright foliage, and that of the elegant is pale and unequal; the leaflets of the latter are also marked with a brown band, like common clover, which is not the case with the hybrid. Another character of the hybrid is, that in the summer, when it begins to shed its blossom, and during autumn, the root throws out fresh foliage, arranged like a rosette; but in the elegant trefoil this does not occur. It is the lateral branches which rest on the ground that supply the verdure. The hybrid trefoil also flowers fifteen days earlier than the other; which, however, lasts the longest and branches more. Lastly, the former is taller, more beautiful, and comes in earlier; but when the latter has arrived at perfection, having more numerous stems, well covered with branches, and more solid, it will yield, when mown, as great a produce as the former. The hybrid trefoil has been a great deal used by M. de Kruns in the formation of artificial fields at Orebo, in Sweden, and it has succeeded well; it has grown from three to four feet high, and has yielded, during about 20 years, often more than 10,000 lbs. per tunnland, (about 1¼ acre English,) and always upwards of 5,000 for the first 10 years. It is looked upon as a plant equally suitable for mowing and for pasturage; strong moist soils, argillaceous or calcareous, suit it well; it frequently comes spontaneously on lands in Sweden that have been drained. The elegant trefoil is found in abundance on poor clayey strong soils, where it grows thick and vigorous. It is wild in France in many places; not unfrequently in ferruginous sand. It seems very probable that the species will one day form valuable additions to our forage plants, as they appear as though they would succeed on lands unsuitable for clover, lucerne, and sainfoin."

An interesting statement respecting the productiveness of Italian rye grass as an early spring feed for horses is found in the Mark Lane Express, as communicated to the Newcastle Agricultural meeting, by Mr. Dickinson. He says that his land, a strong clay in good heart, and underdrained, is finely pulverized during the summer months, after tares, or any early crop of corn. This he sowed broadcast, with grass seed, four bushels to the acre. Harrowed it lightly with bushes, as iron harrows bury the seed too deeply. It was cut the first time in 1844, the first week in March, with about ten inches of grass; April 13, the second time; May 4th, the third time; May 24th, the fourth time; June 14th, the fifth time; July 22d, the sixth time, with ripe seed, and three loads of hay to the acre. Immediately after each crop, the land was watered with two parts of pure urine and one part of water; the produce of each crop increased with the temperature of the atmosphere from one load to three loads per acre. He also had three or four more light crops, the ground having been harrowed with iron harrows, but without manure as before. In 1845, his first cutting was April 6th; second, May 3d; third, June 9th; fourth, 2½ feet long standing in the land, July 12th. He states that the Italian rye grass differs in quality and variety; there are some that bloom at a foot and a half high, but his was of a kind which stood from four to five feet. A Mr. Hunt also used the same kind, sowing the seed which he had from Mr. Dickinson; an acre the 1st of September, 1844, after a crop of spring tares. He manured his ground with ten loads of good horse dung. The second week in April he states that he began to feed it off with ewes and lambs, and they made quick progress, especially the lambs, as the grass produced an abundance of milk. There were forty two couples, and the grass supplied them weeks; giving the ewes chaff and oats, and the lambs peas. They then began again to feed it for want of other food. He took them off from the grass on the 13th of May,

and on the 18th of June mowed the whole for hay, which produced nearly two loads to the acre; this was about five weeks' growth. He adds: "I am satisfied of its being the most valuable plant I know of, especially for early spring feed; it comes to perfection for feed quite as early as rye, and the comparison between the two for feeding qualities is as ten to one in favor of the Italian rye grass." The brown or dark colored, which has a more fibrous stem, is stated by Mr. Rodman, in the Royal Agricultural Journal, to be better than the pale. The last report (appendix No. 28) contained a full description of the Italian rye grass.

A writer in the Cultivator of July, 1845, from Tuscaloosa, Alabama, recommends lucerne, Guinea grass, clover, herdsgrass, and rice grass, as suitable for the south, and urges the cultivation of them upon the attention of the planters of Alabama, &c. He says: "During the winter, I have seen bundles of *northern* hay brought to the stables of my neighbors, which had paid for carriage many hundred miles round the capes of Florida and through the Gulf of Mexico, and five hundred miles by the course of the river into the interior. This is a *standing reproach* to the agriculture of the south." His letter may be found in the appendix No. 7.

The results of an experiment given in the Journal of Agriculture for the purpose of proving the best depth for burying the different kinds of grass seed, show that grass seed is usually harrowed too deep in the ground. The condensed account of the same, as taken from the Cultivator of February, 1845, may be found in the appendix just mentioned. We have also added to the same appendix a paper on the proper time for cutting, and mode of curing grass for hay, giving the opinions of different persons in the agricultural meeting in Albany in the early part of 1845. These are valuable, as embodying the experience of scientific men and practical farmers.

HEMP.

The crop of hemp is almost confined to a few western States. The estimate of the last year, as appears from the letter of Thomas D. Forman, Esq., of Louisville, Kentucky, contained in appendix No. 8, was not sufficiently large. We have taken that which he offers mostly as the basis for the estimate of this crop in 1845.

The notices respecting the hemp crops of Kentucky are as follows. In June: "We learn that the hemp crop of this State and Missouri is in a most promising condition, and bids fair to be greater than in any previous year."—*Louisville* (*Kentucky*) *Courier*.

Later in the season: "We understand that in some neighborhoods the present hemp crop is very deficient both in the quality and quantity of its lint; so much so that it is believed that it will not average one-third the usual crop."—*Lexington Inquirer*.

The crop is variously estimated by others, from whom we have derived information, at from "25 per cent. to one-third more" than the crop of 1844. The following gives an account of the receipts at Maysville: "The receipts of hemp in the Maysville market for the month of October, including a small amount from one of the establishments not hitherto reported, amount to 693 tons; making the total received, shipped, or manufactured for the ten months of the year 1845, up to the close of October, 5,008 tons. We suppose that the amount which will be received in the months of November and December will swell the total receipts of the year to 6,000 tons.

The Hon. A. Beatty stated in a letter last year (see report for 1844) that the receipts at Maysville would comprehend one-third of the hemp crop of Kentucky. The accounts respecting the hemp crop from Missouri are encouraging. We have supposed it to be increased.

A variety of papers regarding the culture and preparation of hemp, &c., will be found in appendix No. 8. Another, also, containing an account of Mr. Billings's mode of culture and preparing it, may be found among the articles in appendix No. 1, mentioned in the letter of Hon. H. L. Ellsworth. Another still, translated from a German journal, contains a description of a mode practised in some parts of Europe, by which the process of preparation by water-rotting is rendered comparatively easy, and the time consumed in the process is very considerably shortened. This, perhaps, still remains the great desideratum to ascertain the best and cheapest method of water-rotting it, so as that it shall compete with the Russian hemp. The modes of breaking it without rotting are all more or less liable to objections on account of injuring the fibre; and numbers of machines for this purpose, respecting which sanguine views have been entertained, have been discarded, on their application to general practice, as unsuitable for the object. The trials which have been made of American hemp, in comparison with Russian, during the past year, it is believed have resulted in satisfactorily demonstrating that the former is fully equal, if, indeed, not superior to the latter. The following scrap from one of the public journals presents the comparative strength of cordage manufactured from the hemp of Indiana, Kentucky, and Missouri. "The experiments, 100 on each kind, of similar appearance and like cleanliness from each State, were made at the navy yard in Boston, and they were made on rope $1\frac{3}{4}$ inch in circumference, viz:

	Indiana.	Kentucky.	Missouri.
Test - -	4710	4474	4195
	4700	4082	4160
	4896	4272	4192
	14306	12828	12547

"Mean strength of Indiana, $4768\frac{2}{3}$; Kentucky, 4276; Missouri, $4182\frac{1}{3}$. The usual test of Riga is 4400 to 4900. It would seem from these trials that the Indiana hemp was nearest the test."

Again: "Experiments were made at Louisville, Kentucky, a few days ago, with a machine for testing the strength of cordage manufactured from hemp, which showed that American hemp, instead of suffering by a comparison with the Russian article, gained by the investigation. In the test of larger cordage, the Kentucky article sustained a much greater weight than that imported from Russia."—*Philadelphia Daily Chronicle.*

The results of the experiments just referred to, and other similar information, will be found stated in the letters of Mr. Sanders, hemp agent, which, with the instructions of the honorable Secretary of the Navy, and several articles from the public journals relating to these subjects, are subjoined in appendix No. 8.

A statement respecting the profit of raising hemp is furnished in the St. Louis Republican, which we quote at this time for the purpose of showing that this crop deserves still more attention than it has yet received: "The

St. Louis Republican says that Mr. T. Longwith, a farmer in Scott county, Illinois, who has, for two or three years past, water-rotted his hemp, and bestowed great care upon it, last year kept an accurate account of the cost of cultivating and preparing for the market the product of 8 acres, including the rent of the land, cost of seed, labor, and expense of getting it to market; and the result was a net profit of $213 38. In estimating the cost of labor, a man's wages was charged at 75 cents per day, and an ox-team at $1 50 per day; but the most of the labor was done by himself and son, and the only outlay paid in money for extra hands and transportation was about $40. The product of the last year's crop from the 8 acres weighed 6,300 pounds, and was sold a few days ago in the market at $115 per ton. The year before he sold his crop here at $125 per ton. He sent a sample of his hemp last year to the navy agent at Boston, who, after testing it, pronounced it, in strength and texture, equal to the best Russian hemp. We must remark, however, that his is the best article which we have seen in this market; but we are assured by him that hemp equally as good can, with proper care, be produced in other parts of Illinois and Missouri."

"Some hemp has been exported to England; but it does not promise a very remunerating price, as we learn that it sold for only £20 to £25. It is, however, well spoken of in the English papers." "The American bark Westheag, which arrived at Dundee, Scotland, in the early part of this month, brought a quantity of hemp, intended to be used for purposes to which flax has been only hitherto applied. It is said to make very excellent yarn of small sizes, but it is feared that it will not bleach so well as flax. The price is so low that it stands the spinner considerably less than the flax, even after the expense of softening (£4 to £5 per ton) has been added. We understand that Mr. Sharp, of Dundee, holds a patent for softening the article prior to its being used by the spinner." Again: "A house in this city, during the past summer, made an experimental venture of fine hackled hemp, by taking out of each 100 pounds 50 pounds of tow, and sending one parcel to Boston, one to New York, and one to Liverpool. That sent to New York was sold early, before the price declined, and brought $170 per ton; that sent to Boston was sold recently at $140 per ton; and that sent to Liverpool is not yet sold, but they are advised by the steamer Great Britain of its arrival, with the following "broker's report," viz: 'Seven bales hemp, good quality, picked and pretty even, worth £21 per ton.' £21 sterling are equal to $101 50, at the present rate of exchange; from which deduct the freight and charges, and there remains but about $45 per ton; whilst that sent to New York netted about $140 per ton, and that to Boston $110 per ton. These $45 are for a ton of hackled hemp; to produce which, two tons of hemp from the farmers were used, worth $130. The tow which was hackled out was worth about $40 per ton; thus making $90 as the cost of what was worth in Liverpool net $45. Nor will hemp in its rough state do much better. As we recently stated, another individual sent some to Liverpool that cost him $62 50 per ton, by which he will lose about $23 per ton."—*Dollar Farmer.*

An account is given in the St. Louis Missourian of a kind of wild hemp found in Missouri, which seems to deserve attention and further investigation. We have not met with any other mention of it. The St. Louis Missourian says "that wild hemp has been found in that State. A farmer from St. Louis county, being in Captain Jenks's hemp warehouse, accidentally saw some Manilla hemp; made inquiry what it was; and, on being

informed that it was Manilla hemp, said he had produced something exactly like it from a weed on his farm, and that he would send in a sample, which he did; and it proved to be a variety of the Manilla hemp, resembling most the New Zealand hemp, but it undoubtedly belongs to the same genus as the New Zealand, Sisal, and St. Domingo hemp, from which all our heavy cordage is made. If this can be found in any quantity, it is a most valuable discovery." The Bear grass is also highly recommended for the same purpose.

Although we have not included *flax* in the tabular estimate, yet it seems suitable to add a few things respecting this article in connexion with the consideration of the hemp crop. The late invention of Mr. Billings, which is applicable to flax as well as to hemp, promises to render this crop more an object to our farmers. Flax is raised also for the seed, in some of the States, in large quantities. This is the case in parts of central New York, where the increase the past year has been 50 per cent. over the crop for that purpose of 1844. A writer in the Cultivator of April last, 1845, from Waterloo, Seneca county, says: "The success of the Seneca county farmers in making the flax crop a succedaneum for the sun stricken fallow, has induced many farmers in the neighboring counties to adopt its culture." Ohio, too, seems to be prominent in such a culture of this plant. An estimate is furnished in one of the public journals which shows that much success attends its cultivation in parts of the great western State of Ohio. Thus, it is said:

"*Flax seed.*—On the opening of the season a good deal of interest is felt in relation to the crop just harvested. The following, taken from the Eaton (O.) Register, is to the point: 'This article bids fair to rank among the most staple commodities of the farmer in this part of Ohio. For the last two years the farmers of Preble county have paid particular attention to the raising of flax seed. The crop this year is about an average one—the drought in the early part of the season injuring the crop somewhat for seed, and still more for lint. Mr. Denny, who is engaged in the purchase of seed, has furnished us with about the probable number of acres, &c., raised in the county this year. Take the county over, it will average ten acres to every section. This would make the number of acres raised, there being 432 sections in the county, 4,320. Calculating eight bushels to the acre, would make 34,560 bushels, which, at 80 cents per bushel, would bring to the farmers of Preble county this year, for this commodity alone, the sum of $27,648.' The above estimate is undoubtedly low enough, not only in the number of acres and average yield, but in the price." Of Cincinnati it is stated: "The manufacture of linseed oil has also here assumed considerable importance, there being six extensive oil mills, which, together, are estimated to use about 150,000 bushels of flax seed yearly. This, at seven quarts of oil to the bushel of seed, will give upwards of 260,000 gallons of oil. The oil cake is principally sent to New Orleans, and there shipped to Liverpool."

A number of interesting articles relating to flax may be found in the appendix No. 9, on this subject. It has generally been believed that flax is an exhausting crop; but a writer quoted in the American Agriculturist holds the contrary opinion. Whether or not the view taken is admitted to be correct, it may at least deserve some investigation. In a paper read by Dr. Kane, before the Royal Irish Academy, he attempted to prove that in the production of the fibre no exhaustion of the soil takes place; that sub-

stance being exclusively composed of organic matter, derived from water and the atmosphere. He says that in this respect the fibre differs from the woody system which surrounds it, as the latter, by combustion, yields a considerable quantity of ash, consisting of inorganic compounds, derived from the soil. The woody part is not removed from the farm, being of little value. The proportion of inorganic matters contained in the seeds is very small, compared with its entire bulk, so that, if consumed on the farm, flax is not an exhausting but a restorative crop."

The same opinion is expressed by G. Nicholls, esq., in the Royal Agricultural Journal of England. He says: "It has often been said that flax is an exhausting crop, but it certainly is not more so than many of the usual grain crops, nor does it require a very rich soil. Indeed a rich or highly manured soil is injurious, causing the plant to grow too strong and luxuriant, and rendering the fibre coarse and less valuable. Flax is grown on light poor land in Belgium and Holland, and I have seen it growing on mere bog in Ireland."

In the Mark Lane Express of July 18, Mr. Warner says that, under the improved system, the seed of flax is preserved without deteriorating the fibre, and thus the crop is rendered doubly valuable. It must, on no account, be mowed or reaped, but pulled up by the roots. The best criterion for judging of the proper time for pulling it is precisely when the major part turns yellow, and the kernel of the principal ears brown. It is better to begin too early than too late. The method of pulling is merely to collect a small quantity in the left hand, and to pluck it with the right hand, placed about half-way down the stalks. The hands thus being quickly filled, it should be neatly spread in even rows on the ground. In the course of a day, or as the weather may be, turn it with a stick. When dried to the state in which hay would not heat in the stack, tie it in small sheaves about two feet in circumference, and put it in a barn or stack it. If tied up before dry, set it up in the field, pull out the weeds, tie long and short stalks in separate sheaves, &c.

The subject of flax was discussed also in one of the meetings of the Farmers' Club, in New York; and we have given some extracts from some of the opinions there expressed, in appendix No. 9.

The papers read before the society for the improvement of flax culture in Great Britain, as they are contained in the agricultural papers of that country, have presented many important facts in relation to this crop. One containing directions for its culture and management we have inserted in our appendix No. 9, from the American Agriculturist of November, 1845. In some of the foreign journals, also, we find statements respecting the statistics of flax, which may be useful for reference. The yearly product of flax in Belgium is 2,560,000 cwt., three-fourths of which is from the two Flanders. The value of this harvest is said to be $3,400,000, and for it there is required 15 to 17,000 acres of land. By breaking, rotting, and drying, the weight is lessened one-half, and it then equals $4,000,000 in value. By swingling and hetcheling, the weight sinks to 360,000 cwt., but the value is thus increased to $6,720,000; so that by the continued improvement of the flax it doubled in value by each process. The amount of flax and tow imported into the United Kingdom of Great Britain is stated by a writer in the Journal of the Royal Agricultural Society to be, according to Parliamentary returns, 1,437,150 cwt. This is derived principally from Russia,

Prussia, Holland, and Belgium. About 100,000 cwt. of hetcheled flax is exported from Belgium to other countries.

An interesting letter on flax and the linen statistics of Austria, furnished by Mr. Fleischman, may be found in appendix No. 9, extracted from the Washington Union.

A species of flax, called the Chinese flax, has been mentioned in some of the agricultural periodicals as furnishing goods which resemble French cambric, having a silky appearance, and which, it is stated, possesses more valuable properties than flax, owing to the length of staple and strength of fibre. It has been suggested as a valuable staple, which might be added to our products, but we have seen no particular description of it, or of its habits, culture, &c.

In Dingler's Polytechnic Journal for July, 1845, is an account of a new spinning plant, a species of *urtica* or nettle, which is stated to have been brought from China to France, and which is recommended there for trial.

TOBACCO.

It is believed that increased attention is paid to the culture of tobacco in some of the New England States, though they cannot in any proper degree be considered tobacco growing States. The fertile lands in the Connecticut valley, from Hartford up to Northampton, have within a few years, furnished very respectable crops of tobacco, and the produce of the crops there is said to be very good for the manufacture of cigars. The following are some of the notices we have gathered respecting it in the two States of Massachusetts and Connecticut, and by which we seem authorized to infer that it is a profitable and increasing crop in that section of our country.

The Springfield Republican (Massachusetts) says: "The cultivation of the tobacco plant has been very largely entered into in this town and vicinity within a year or two. One gentleman of this town has 26 acres of it this season. When successfully cured it proves a very profitable crop, but its cultivation requires much care, and it exhausts the soil in a large degree."

A correspondent of the Brooklyn Gazette says: "Tobacco is getting to be a great article in agriculture all along the valley of the Connecticut, and it is said there is no land in the world that will produce so good and as much per acre as our land will. I have about three acres growing for the first trial, and if it prove a good crop I shall continue the cultivation of it."

A correspondent of the Dollar Farmer (Ky.) says: "Though the season has been dry, the tobacco crops in Connecticut, I think, are much heavier than any I have seen in Kentucky. It is planted very thick—2 feet one way by 30 to 32 inches the other—thick planting being requisite for good cigar leaf. To this secret of thick planting the Mason county (Ky.) tobacco is indebted for its celebrity; and it is worthy of note that the secret was brought out to Kentucky by some Connecticut tobacco buyers. 2,000 lbs. of tobacco to the acre is said not to be unusual in Connecticut."

Again, in the New York Farmer a correspondent says: "As the growing crop of tobacco is receiving attention and is raised to good profit, I must give you an estimate of the cost to raise one acre, made by myself, with the help of friend L.; and he should know, as he has several acres which average one ton per acre, and sells at Warehouse Point for eight cents per pound, or $160 per ton. Mr. L. says one ton per acre is a good crop, and probably more falls short than comes up to it. Now for the estimate:

Use of one acre of land, one year			$15 00
10 carts of manure at $2 50	25 00	one-half is	15 00
Carting and spreading,	5 00		
Ploughing twice			3 00
Harrowing and marking			1 00
7,000 tobacco plants, sold at 50 cents			3 50
Holeing and setting plants			3 00
Hoeing 4 times			5 00
Extra attendance to secure and kill worms			2 00
Topping and securing			4 00
Cutting and hanging up to dry			4 00
Stripping from stalk and packing			5 00
Rent of shed to dry in			4 00
Freighting to Warehouse Point			3 00
			67 50

"Now, $67 50 from $160 leaves a net profit of $92 50 per acre. Now, what crop other than tobacco would make so good a return? This is a fact worthy of consideration."—*Northampton*, *November*, 1845.

The increase in these two States, we believe, may fairly be estimated at 20 per cent. over the crop of the preceding year.

In New York, tobacco was not included in the returns of the late census, and therefore we are unable to form any tolerable estimate respecting it. In Pennsylvania, in the tobacco district, which lies principally, as appears from the census returns, along the Susquehannah river, there seems to have been a small gain. The early accounts respecting the tobacco crop of Maryland were very discouraging. We subjoin a few of the notices gathered on this subject. The tobacco growing region lies principally on the western side of the Chesapeake bay, and includes Prince George, Calvert, Charles, and Anne Arundel counties. In April, the Upper Malboro' Gazette, Prince George county, says: "For several days past the weather has been cold and blustering, and serious apprehensions are felt for the plants of the second sowing of tobacco seed. The first was killed some weeks ago, and the beds re-sown. A continuation of this weather for any length of time must so far retard the plants as to render a short crop inevitable."

Again, in May: "The prospect for a tobacco crop is rather gloomy at present. The fly is making sad havoc with the young plants, and will continue to destroy them so long as the harsh weather continues. This time last year many farmers had commenced planting their crop; now, we know of some who were sowing their seed for the third time on the first of this week. The crop must be far below an average one." The Leonardtown Beacon, in July, speaking of this crop, says: "The tobacco crop, we think, will fall short of the crop usually raised, but not to that extent which was at one time anticipated. The rains which have recently fallen have had a very beneficial effect upon the tobacco planted late, which now bids fair to make the farmer ample returns for his labor. It is impossible, though, we think, that this tobacco can cure well, as it must necessarily be cut in a green state; the season being now too far advanced to admit of its ripening. The most of that which was planted early in the

season has been already cut and housed, and the rest will be sufficiently ripe to cut in the course of a few days."

The American Farmer also says: "The tobacco plants severely suffered by the frosts and drought, but the very favorable weather which the planters have enjoyed since the middle of June will, we trust, have caused a decided improvement in their prospects of a crop of this great staple of Maryland and Virginia." Yet later—the accounts are in October. The Port Tobacco (Maryland) Times says: "The tobacco crop, from what we learn, has been with us an average one, but we are apprehensive that the hasty manner in which some of it was housed, and the recent wet and unfavorable weather for curing it, may have had a tendency to change its complexion." The St. Mary's Beacon of the 23d says: "We understand that several of our farmers had their tobacco seriously injured by the frosts which fell during the early part of last week."

The Marlboro' Gazette of October 17 says: "Last Thursday, Friday, and Saturday were very unpropitious days for the tobacco crop. Almost every one had housed their crop, and the close, damp, and rainy weather at this stage of curing soon rots it. Friday, in particular, was most injurious. We have not learned the amount of damage, but it cannot be inconsiderable, judging from the quantity recently carried to the house; hurried there, in many instances, from a fear of frosts. Fears are entertained that the unfavorable weather for curing tobacco in Charles county, and the frosts in St. Mary's, have seriously injured the crop." We are informed, however, that a larger quantity than usual has been inspected in the Baltimore market. The American says: "The quantity of tobacco which will be inspected at Baltimore the present year will exceed 60,000 hogheads; a larger amount than was ever inspected at Baltimore in any one year, and about double the average of inspections from 1825 to 1828." Notwithstanding the apprehensions expressed therefor, we believe that the crop was considerably larger than that of the previous year, which, it will be recollected, fell off from that of 1843. The omission of the millions in the table for this State the last year, (a clerical error, which was corrected in most of the printed copies,) will be recollected. We have restored the proper numbers in the present estimate.

Virginia is among the foremost tobacco growing States; but for a few years past the crop in this State has not been so successful as formerly. The early notices respecting its appearances the past season were unpromising. Thus, the Petersburg Intelligencer of April 15, speaking of the frost and cold winds, says: "The second sowing of tobacco will produce but few plants, and a third must generally be resorted to."

So, in May: "Great complaints, too, have reached us in respect to the tobacco plants. Many planters indulge the apprehension that the injury is irreparable, and that under the most favorable circumstances not more than half an average crop can be reasonably anticipated."

The Richmond Compiler says: "There was at first, as is usually the case, an alarm about the scarcity of tobacco plants. It is now thought, however, that there will be generally enough to plant the crop. Plants are more abundant than they were last year. There was great complaint on Dan river last spring; we learn that there is very little now."

In July, also, a correspondent of one of the public journals, under date of Richmond, states: "With regard to the tobacco crop, many doubts are entertained, on account of the want of rain. Reports from the counties between this city and the Blue Ridge are very discouraging. Not one in

a hundred of the tobacco planters have this year put in the ground more than one-half their usual quantity; and that is perishing from the drought. The region of country above alluded to is one of the principal tobacco districts." "The tobacco crop, the Virginia papers say, must necessarily be short; not more than half a crop has been planted, and the want of sufficient seasons has caused it to *stand* badly, and but little will be topped before August. The Lynchburg Virginian says that many planters in that region have been unable, for want of a season, to plant as much as usual; and no small quantity of that planted has since died, or has been materially injured." In August we meet with conflicting accounts.

Thus, the Richmond Whig of the 28th says: "The tobacco is in very many cases the largest ever known or seen; and, by its unusual size, will bring up the crop to an approach to average far beyond anticipation."

Other journals speak very discouragingly. Thus, a letter from Albemarle county, dated the 25th, states that, on account of the drought, "the tobacco crop will be very light indeed. Some of the farmers have been obliged to send 40 miles to supply their farms with meal."

Again: "The tobacco crop will be, beyond all question, a short one. In the counties below us, as well as here, the planters did not succeed in getting an average crop planted; and since it was put in the ground the season has been most unpropitious. The plant is now becoming prematurely ripe in many places; and in others, the bud has been blighted by the excessive heat of the sun. There can be no doubt but that there will be far less than the usual crop brought to the house."

In September, also: "The Virginia tobacco crop is likely to turn out small; not one in a hundred of the tobacco planters in the best tobacco growing region have planted more than half their crop, and that is perishing from the drought."

"A Charlottesville letter, published in the Richmond Whig, says that the tobacco crop in Buckingham, Amherst, and Nelson counties, Virginia, will not exceed more than half the usual yield. Albemarle, it is also stated, will fall short one-third."

Still later, we are told by one who has traversed the valley country—"The most sanguine do not count on half a crop of tobacco. Some neighborhoods are worse than others; but all are bad; and from numerous inquiries, I fear it is generally the case in Virginia, between the Blue Ridge and the head of tidewater."

Again: "From all I can learn, I am satisfied that there will not be more than half a crop of tobacco in Virginia this season. The season was unusually unfavorable for planting, and hence the stand is greatly less than what it otherwise would have been; and then, from the dry weather, the yield from what is standing will be small. The recent rains have been very copious, and will prove very beneficial to the tobacco and to the later planted corn. I observe some tobacco planted since the rain, and this, with a late fall, will yield well." The Lynchburg Virginian says, that "a great deal of forward tobacco that had been cut and hung in the open air for the sun-curing process was injured, and some of it destroyed by the heavy rains on the 10th and 11th October."

In the Southern Planter for October, we find similar estimates: "The growing crop of tobacco in Virginia must, we presume, from the nature of things, be a very short one. The early season was very unpropitious to the growth of plants, and every man that had cabbages to set out knows

that it was almost impossible to obtain a 'stand.' The drought must have seriously affected those plants that did live, and we greatly fear that the August rains were very productive of fire and rot. From what little we know of the crop, we should imagine that, take it through and through, a worse season could hardly, in the course of nature, occur again."

Again, from a correspondent of the same journal, who writes from Mecklenburg: "In relation to the amount of the tobacco crop planted, you will have a variety of statements. The general opinion here is, that not more than half a crop was planted till the August rains set in; that part cannot make tobacco. The first plantings are very badly missing, but have improved surprisingly, and now promise to make good tobacco if we have a late and favorable fall."

Our other information is of the same cast, generally. Thus, one writes to us respecting the eastern central section of the State, lying east of the Blue Ridge: "The crop will scarcely reach half the usual average. Plants, owing to the late frosts and dry spring, were very scarce, so that but little (if any) more than half the usual crop was planted. The plantings, too, were unusually late, so that there is much danger even yet, (October 6th.) A large quantity must be cut in order to save it from frosts. Upon the whole, I feel very certain, after very particular inquiries, that the crop will not, as before observed, reach the usual one." Still further to the east, the decrease is estimated at "25 per cent. less." In the central southern section it is thought to have fallen off as much as "33⅓ per cent.," and in the northwestern corner of the State to have been "one-fourth less" than the crop of 1844. Although the crop was much less than an average one, yet the fact must be taken into consideration that it has decreased largely for a few years past. The decline, then, from the past year's crop, may not exhibit so large a falling off as it otherwise would. We believe that, on the whole, it has not fallen off more than about 15 to 20 per cent., if even this decline may not, perhaps, be too large.

The tobacco crop of North and South Carolina suffered also severely by the drought, and in some places fell off 25 to 30 per cent. The millions omitted by a clerical error in the table of the last report, for North Carolina, have been restored. In Georgia, the injury appears not to have been equally great; and in some parts of this State, we are informed there has been increased cultivation of this product. The crops in the northwestern part of the State have been good.

More attention is now paid to the culture of tobacco in Florida. The following statements are gathered from the public journals in relation to this subject:

"*Tobacco in Florida.*—The low price of cotton last year induced the planters in Walton, Washington, and other counties of Florida, to raise tobacco; the result was so favorable, that this year they are going into the culture on a large scale."

Again: A letter recently received from Florida shows that this new member of our family of States is about to set up a rivalry with old Virginia, as to which is to be hereafter the tobacco State of the Union. It says: "Every body here is going into the tobacco culture, which promises to replace the orange, as it requires no machinery, and the poorest can engage in it. The experiments that have been made, notwithstanding the worst season ever known, have proved extremely encouraging. The article is of a superior quality, and commands a high price in New York—from 40 to 80 cents.

H——, who has just arrived from thence, states that the choice qualities will command this latter price. There will be much done in it here the next year; and there is every prospect of its becoming the staple of Florida." We have felt justified, accordingly, in giving a very considerable increase to the tobacco crop of Florida. It is stated in some of the public journals that 1,000 to 1,500 pounds have been raised on an acre in Tallahassee."

There has been some increase, also, in the crops of Alabama and Mississippi.

The tobacco crop of Tennessee, in the northern part of the western district, as we are told in July, was very promising. In some portions of the State, however, it was more unfavorable. At a later date we learn that there was about an average crop in the State, which, as the crop of the preceding year was also an increase on that of 1843, we suppose will give a moderate gain.

The early accounts of the tobacco crop of Kentucky were unfavorable. The late frosts in the spring, it was thought, would so greatly injure the crop as very much to cut off the hopes of the planter. Thus we find it stated in April:

" *Green river (Ky.) tobacco crop.*—The last number of the Hopkinsville Gazette has the following: 'The heavy frosts and cold nights of Monday, Tuesday, and Wednesday last, have, we are informed, injured the young tobacco plants terribly. One gentleman told us that his were all killed, and that he had burnt new beds and sowed again, but without expectation at this time of the season of being able to raise any plants. Should this be the case generally, (and, as the ground was frozen half an inch or more, we see no reason why it is not,) the tobacco crop of this section will fall short immensely.' "

Again, the Maysville Eagle of May 24 says: "The scarcity of tobacco plants, even if the season for planting be not too far advanced, will operate to produce a short crop in this region."

The crop, however, proved better than had been anticipated. In some places, indeed, it was only tolerable, while in others it is said to have been "very good—in quantity perhaps not quite equalling that of the last year," but in quality surpassing it, and in value fully equal to it. The planters, we are told, "do not *fire* their tobacco as much in curing it as formerly." There are several stemmeries in the State, in which large quantities are stripped and prepared for the British market.

In parts of Ohio considerable attention is paid to the cultivation of tobacco. " The editor of the Liberty Advocate, of Cadiz, Harrison county, says that in passing through Guernsey county, he was much surprised to see the vast amount of tobacco raised by the farmers. Almost every farmer had his tobacco, and a great many paid little or no attention to any other branch of agriculture, on the ground that no other work so abundantly repaid labor." In Miami township, we are informed that there was raised 200,000 pounds; and in the southwestern section of the State the increase is estimated at "25 per cent. more" than in 1844. The crop may have been from 10 to 15 per cent. more.

The same was probably the case in Indiana and Illinois. Indeed, in some parts of these States, the increase is thought to have been as high as "20 to 30 per cent." This, however, would probably be too great an average for the whole State.

The earlier statements respecting the tobacco crop in Missouri were most

unpromising. Thus it is said in the St. Louis Era, May 5: "Those engaged in the tobacco cultivation have had a good opportunity to put their ground in a proper state of preparation, but the planting season of that crop has not yet arrived."

As the season advanced, however, the prospects brightened; as we learn from the St. Louis Republican, of July 2, that "the crop of tobacco is better than was anticipated in the early part of the season." Yet, in some sections, there was not the same success in its culture. The Hamilton Journal of July 24 says: "The tobacco crop in this section, so far as we can learn, is next to a total failure; owing, we believe, to the fact that the early part of the season was so dry that it was impossible to rear the plants. We are informed, however, that further in the interior, and on the Missouri river, the prospect is more flattering." The Fulton Telegraph also says: "We should not speak of a tobacco crop in Missouri this year at all; there is an almost entire failure in plants; there are loud complaints."

In September the Glasgow Pilot says: "The tobacco crop, which has been very promising in this neighborhood, is very much injured recently by the tobacco worm, which is more destructive than has ever been known here. We have ridden by several fields of tobacco, the leaves of which are tattered by them as if cut up by a severe hail storm. The old ground seems to suffer most."

Again: The St. Louis Republican of the 12th instant says: "We are sorry to hear dismal accounts of the coming tobacco crop in this State. In many if not most of the counties on the Missouri there has been a very general failure of the plants in consequence of the cold and unfavorable weather; and those who persist in attempting to raise them must rely on the most favorable aspect of the weather to bring them to maturity. In Franklin county, noted for the production of our finest tobacco, the planters are substituting corn, and elsewhere others are putting in hemp. Unless a very great change takes place in the prospect, there will be an almost entire failure in the tobacco crop. Timely rains have improved the prospect in the country bordering on the Mississippi." There was, on the whole, probably an increase, though not large, as there was a considerable falling off the year before.

The whole tobacco crop, therefore, for the United States, may be estimated at 187,422,000 pounds; which is about an average crop, as it is nearly 10 per cent. above that of the year before, which probably did not equal an average one.

The quality of some of the crop is spoken of as fine. Thus one of the public journals says: "We clip the following from a St. Louis paper, from which it will be seen that there is an advantage in raising good tobacco as well as good anything else. 'The first premium for the best manufacturing tobacco, at the planters' warehouse, a few days since, was taken by Samuel Jeffries, of Franklin county. It was afterwards purchased by T. Campbell, of this city, for the high price of $22 25 per hundred pounds. The second was taken by W. E. Wells, of Pike county, and was bought by Price & Perry for $20 25.'"

The following statements respecting the exports of tobacco from New Orleans we find also in one of our papers, and give it, as it furnishes some idea of the progressive importance of this crop:

"*Exports of tobacco from New Orleans.*—The shipment of tobacco, it will be seen, has been nearly tripled within the last 10 years from the port

of New Orleans, and is within a fraction of the entire quantity exported from the United States in 1833—83,153 hogsheads. It has more than doubled itself, it will be seen, since 1840; thus showing what rapid progress is being made in the production of the weed in the western States. A large quantity of western tobacco also finds its way to the port of Baltimore, by the internal improvement lines. The price of tobacco in Europe in 1840 averaged $81 05 per hogshead, whilst in 1844 it averaged only $60 11. Tobacco shipped from New Orleans for the last ten years:

1835	33,801	hogsheads.
1836	41,634	do.
1837	35,821	do.
1838	31,555	do.
1839	30,780	do.
1840	40,436	do.
1841	54,667	do.
1842	68,058	do.
1843	89,891	do.
1844	81,249	do."

In one of the agricultural papers we find quoted an account of the amount of tobacco inspected at various places, including the Virginia and North Carolina crops, with an opinion respecting the crop of last season by a firm in Virginia. We subjoin it, in order to aid any one who may wish to compare it with that inserted in the former report:

"*Virginia tobacco.*—The following statement respecting the inspection, exports, and stock on hand, of Virginia tobacco, for the year ending 30th September, 1845, is published in the Richmond Times of the 7th instant:

		Inspections.	Stock.
	Richmond	21,902 hhds.	13,750 hhds.
	Petersburg	11,151 "	1,528 "
	Lynchburg	10,692 "	4,656 "
	Clarksville	2,986 "	38 "
	Farmville	3,245 "	322 "
325	Danville, Milton,		
425	Tye River,	1,150* "	150* "
400	Henderson,		
		51,126	
1150	On ship board, not cleared		1,500 Un-
	In transitu from upland inspections		500 count'd
			22,444

"*Foreign exports.*—Liverpool, 4,707 hogheads of tobacco; London, 1,187; Bristol, 664; France, 4,542; Trieste, 401; Genoa, 1,647; Bremen, 1,281; Hamburg, 435; Rotterdam, 1,365; Amsterdam, 477; Antwerp, 1,018; Rio de Janeiro, 1; shipments via northern ports, 1,000. Total, 18,725 hogsheads. To Bremen, 2,622 hogsheads stems; to Rotterdam and Amsterdam, 560 hogsheads stems; shipped via northern ports, 1,500 hogsheads stems. Total, 4,682 hogsheads stems.

* Conjectural.

"*To the editors of the Times and Compiler:*

"GENTLEMEN: We give above the statistics of tobacco inspections, stock, and foreign exports, for the present fiscal year, ending 30th ultimo. As regards the inspections, they have been increased several thousands by reinspecting reprized tobacco. In reference to stock, a large portion consists of crops inspected in 1843 and 1844, nearly all of common quality. In reference to the product of Virginia and North Carolina this year, there have been throughout the season conflicting opinions entertained. The planting in May was probably equal to about one-half an average crop. The drought early in June till the 1st of August was so intense and general as to prevent planting to much extent; yet in some neighborhoods there were occasional favorable seasons for transplanting; and such opportunities being embraced in June and July, probably made the entire planting to 1st of August equal to 35,000 or 38,000 hogsheads. From 1st to 10th August, perhaps, the plantings were equal to 5,000 or 6,000 hogsheads. Since the 1st of August the weather has generally been as propitious as could have been desired to hasten the growth and mature the tobacco crop; and should there not be a killing frost before the 20th of this month, the crop produced this year will be about 38,000 hogsheads of merchantable quality.

"Respectfully,

"JONES & BLAIR.

"OCTOBER 6, 1845."

In a letter received by the late Commissioner of Patents in March last from Dr. Muse, of East Cambridge, Maryland, well known to the agricultural public, alluding to a parcel of Spanish tobacco seed sent by him to this office, he says he has manufactured remarkably fine cigars from the leaf raised by himself from seed imported direct from Cuba—"they will equal the famous regalias." He says that he prefers the "principe" tobacco, but has never but once (seven years ago) obtained that variety. He states that his cigars from that tobacco were admired in New York, at Saratoga, and Philadelphia, and every where, by the most fastidious in taste. He sold them for $14 per box of a thousand cigars each. His crop for the year 1845 he estimated at that date would amount to 600,000 cigars, which he intended to manufacture himself on his plantation.

Several interesting papers, relating to the culture of tobacco, &c., taken from various agricultural papers, will be found in appendix No. 10. Among these is a description of the mode of cultivation in Connecticut and Kentucky, taken from the Dollar Farmer, the editor of which remarks that the same kind ("the fine cigar leaf") is cultivated in both States, though the soils are quite different. In Connecticut the plants stand about 3 feet apart, and in Kentucky 3½ feet from each other. A paper, also, on the Cuba mode of cultivation, from the Floridian, and W. W. Gilmer's (of Albemarle, Virginia) method, from the Southern Planter, and Mr. Venable's observations on the spot in tobacco, also from the Southern Planter, will be read with interest by those engaged in the cultivation of this product.

COTTON.

The cotton crop of our country is one of deep and absorbing interest to a large portion of our population. It is one which exercises great influ-

ence over our commercial progress and enterprise, and influences to a wide extent our relations with foreign nations. It is desirable, therefore, to obtain as accurate a history of its growth, from year to year, as may be in our power. Yet there is scarcely, perhaps, another crop respecting which we may not reach more approximating correctness at the period at which our estimates are made. The very fact that it is of so mighty an influence, and enters so largely into the whole foreign market of our country, renders it less easy to know what to believe of the accounts which we meet with in the various public journals. Not that there is any want of materials, such as they are; for the notices of the crop are most frequent. But the difficulty lies in ascertaining what reliance may be placed on them, and how far the different, and often conflicting reports, must be set down as designed to subserve private interest. Such materials, however, as we have, we have endeavored to apply; and if we have failed sometimes in drawing conclusions, we believe that the same difficulty would be experienced by almost any one, and perhaps many would not be even as successful in approaching to the true state of the case. From all that we can learn, the aggregate of the crop, as estimated last year, was nearer to the annual report finally made up from the receipts at the principal ports than were the conjectures of many others about the same period in which we made the attempt.

The quantity of cotton made in Maryland and Virginia is so small, comparatively, that it will scarcely affect the estimate. The drought probably lessened it somewhat.

In North Carolina the same evil, as we have seen in treating of other crops, was most severely felt, and the estimates made vary from "50 to 75 per cent." less than the last year's crop. This is probably too high an average; but we believe it must have fallen short at least "about one-third."

In South Carolina, in June, we are told that "the cotton crop, in some sections, will be very good. That which was planted early is promising, while the late crop will be indifferent." Again, in the same month: "*Forward cotton.*—A subscriber of ours in Edgefield district (says the Hamburg, S. C., Journal) informed us, on Wednesday, that he had plenty of cotton squares on his field, and that within ten days or less he would send us some blooms." Again, in July: "*Early cotton.*—The Edgefield (S. C.) Advertiser, of the 19th instant, says: Colonel F. W. Pickens has left at our office some cotton bolls which were full grown on the 4th instant. They were pulled from one of his fields at Edgewood, near this place. We understand that cotton is beginning to open at the same plantation." In Pendleton, it is said "cotton is flourishing; and though the plant is not so tall as usual, the number of bolls is greater."

Discouraging accounts, however, are given of the Sea-island crop in the same month. "In South Carolina the excessive heat has destroyed every thing but cotton, which stands drought better than anything else. This crop on the Sea islands is, according to the Courier, in a peculiar situation. The early planting in March came up and grew kindly, and still promise well. The early plantings, in April, are half up, and the fields show an irregular stand of plants from 6 inches to $2\frac{1}{2}$ feet high. The latter plantings did not come up till the 20th of May, and are of course unusually backward, and exposed to the vicissitudes of storms, caterpillar, and early frost. It is possible, but is by no means probable, that the plant may escape all these

liabilities, and it is therefore safe to calculate the Sea island crop of 1845 at a product decidedly short of last year."

In August, too, the notices of the crop in this State are of the same diverse character, thus: "The Columbia South Carolinian, of the 14th, says that six bales of new cotton were received at that place on the 8th instant, from the Cane-brake plantation of Richard Lowdley, esq., in Newberry district, and put in store in expectation of a short crop."

Again, under date of August 1st, the Charleston Patriot says: "*The season and the crops.*—We learn by private intelligence from the interior, that the drought continues distressingly severe. In Richland, Lexington, Orangeburg, Barnwell, and other middle districts of the State, the most sanguine expectations do not look to make half a crop. Even on some of the best river swamp lands, along the Edisto, where a thousand weight of seed cotton might be made to the acre in seasons ordinarily favorable, we are told that 100 would be a fair calculation."

The accounts we have received from other sources, of a later date, are of a similar discouraging character. Thus, in the northwestern part of the State, the crop is supposed to have been "25 per cent. less" than that of the previous year. East of this, and bordering on North Carolina, the drought was felt yet more severely; and the failure was very great, and is even estimated as high as "one-half or three-fourths" of the whole crop. In the western central section, bordering on Georgia, it was probably "about one-third less;" and in the central portion of the State, "about 30 per cent. less;" while, of the section still further to the east, central, on the coast, &c., it is stated that the crop was "about the same." The drought was indeed great, but the cotton crop is said not to have been so much affected, and the favorable fall (frost coming very late) matured the late crop; so that, upon the whole, it is considered that "the present crop will not fall much short of that of the previous year." Taking into consideration the fact of the drought, and the emigration which is yearly going forward from this State, of cotton planters, still further west; that the cotton lands are running out, and scarcely any new lands to be brought under cultivation for this purpose, we believe that the cotton was considerably lessened the past season, and therefore fix the decrease, according to the best judgment we can form respecting it, at about 20 per cent. as compared with the crop of the preceding year.

To a more limited extent, the same remarks we have just made as to the causes of the decline of the cotton crop of South Carolina will apply to that of Georgia. We subjoin such notices as we have selected, to give a view of the progress of the crop in this State. In June, "accounts from Georgia represent the prospects of the cotton crop to be good. The plants had begun to blossom." The Albany (Geo.) Patriot says that "the crops, generally, in that vicinity, notwithstanding the drought, promise an average yield."

"The rain with which we were favored on Wednesday last, and which was much needed in this section of country, we are glad to hear extended as far south as Darien. The crops throughout Camden, Glynn, McIntosh, Liberty, and Bryan counties, had suffered much for want of it; and several planters, we hear, had replanted a portion of their cotton crop, while a number had planted in the dry gound, and were patiently awaiting a rain to sprout the seed."—*Savannah Georgian.*

Again: "The drought, which has been general throughout the south,

has in Georgia been severe. Crops are injured in Alabama, Georgia, and the Carolinas, to an extent heretofore unknown. Cotton will be cut short at least one-third."

So, in July: "*Milledgeville, Georgia, July* 1.—*The weather.*—In this section of Georgia we are passing through a severe drought, and the weather is, as usual under like circumstances, excessively hot. Cotton, of which our planters have put in their usual crop, seems to sustain itself wonderfully. The complaint of drought is extensive; but we notice with pleasure that our northwestern counties, and the adjoining portion of Tennessee, have abundant rains."

Again: "From the various sections of the State we regret to learn, through the delegates to the convention, that the drought has been unparalleled; in some parts there has not been rain in two or three months, and all kinds of vegetation has been burnt up; while, in other places, although the drought is not so severe, scarcely one-half or one-fourth of a crop will be made. Thus far, cotton has been less affected than any thing else; indeed, it has not been injured a great deal; but, unless the season changes soon, that, too, will suffer."—*Milledgeville (Ga.) Journal.*

In the Savannah Republican: "The cotton in the interior has not suffered so much; yet it is not at all probable that there will be more than two-thirds of a crop made, unless the fall should be an unusually late one. Extract of a letter to the editors, dated Jacksonville, Telfair county, 5th July.—'Our crops are injured so much in this county that we shall not make more than half a crop on the average; yet we are better off than the surrounding counties.'"

The Macon Messenger, of July 15, says: "Our superior court is now in session, and we have had opportunities of conversing with many of our country friends. They represent their stands of cotton in general to be very good. In Upson and Houston, they are said to be unusually promising. In Talbot and thereabouts, not so good. In Lee, very good. We have heard of some instances where the stand was poor; but in these cases the cause rests with the planter: the fault was in his planting too late, and in not giving proper attention to his ground."

The Savannah Republican, of the 11th, states: "Yesterday we had the heaviest fall of rain since the 1st of January. The cotton crop in the interior has not suffered so much; yet it is not at all probable that there will be more than two-thirds of a crop made, unless the fall should be an unusually late one."

In August, likewise, a public journal makes the following remarks: "There is strong talk of a very short crop. The season has been unusually hot throughout the country, and over extensive sections very dry. At the south the drought has continued for months, so that cotton put on board boats in the spring has not yet reached the coast. We give below several statements and extracts from letters, which we have no reason to suppose were made for effect, and they come from persons likely to be very well informed."

EXTRACTS OF LETTERS.

"*Macon, August* 16.—There is no question now but the crop must be short. No sort of weather can bring the plant and bolls to maturity. In Georgia, I have now no idea that over five eighths of an average crop will be made. In many counties it will not be over one-half to one-third. If our receipts here are 75,000 bales, it will be as much as we may expect.

Mr. ———, on his way to Gainesville, saw three of his acquaintances from Mississippi. They said that till within three weeks before they left home the season had been favorable and the prospects good, but since that, in consequence of the drought, the crop would be cut short one-third. In some parts of Alabama, the crop has suffered. Mr. ———, from Twiggs, says he shall not make over five-eighths of a crop, and his cotton was more promising than that of most of his neighbors. Mr. ——— was here yesterday, and offered to take 20 bales for his crop. He made 90 bales last year from the sown ground. Some planters from Jasper county say that they shall not make 100 lbs. to the acre."

"*Macon, August* 20, 1845.—There cannot be more than 75,000 bales received in Macon. Last year 136,000 bales were received at Macon."

A writer also from Griffin, Jefferson county, says: "Cotton is small and stunted, and although it can do with less rain than corn, will fall considerably short of an average crop throughout the State. In the upper counties the seasons have been more favorable, and the crops are good."

Again: "*Savannah, August* 23.—Our cotton market, if it can be said we have one, remains without change, and during the past week we have not heard of a solitary bale changing hands. The accounts from the interior are more and more gloomy every day of the growing crop; and unless we are greatly favored, the crop in this State will be materially cut off."

Again: "We have cherished the hope for some time past," says the Macon (Geo.) Messenger of the 21st inst., "that a change of the season might materially benefit the prospects of the cotton crop. But the drought has now so long prevailed that very little benefit could be derived from a change of the season. It is only in very limited sections of the State that the crop can be a middling or an average one; in other parts it must be a very short one."

A correspondent of the Columbia Enquirer, a planter, who states that he has lately travelled 300 miles in the heart of the State, says: "The cotton crop is in a precarious state, and there is not the slightest prospect of an average crop in this State. A few days more will seal its fate. The failure of the cotton crop will greatly aggravate the suffering of the people of Georgia."

A public journal estimates the Georgia crop at three eighths of the average yield, and in some counties of the State one-eighth to one-half. "Some planters in Jasper county say they will not make 100 lbs. to the acre. At Macon, it is estimated that not over 75,000 bales will be received this year against 136,000 in 1844–'45."

The subsequent accounts are more favorable. Thus in October, the Milledgeville (Geo.) Recorder says: "Our unusually mild fall has changed in a slight measure the prospect through this portion of the State, in reference to the yield of the cotton crop. From all we can now learn, from all sources, as well as from personal observation—which, by the bye, has not been limited—we have come to the conclusion that, from the late growth having more fully matured than was at one time anticipated, there will be realized about two-thirds of a crop. The article in general, however, will not be found as good staple, or be altogether as fair in quality, as usual. This arises from the bolls having been prematurely forced open by the drought before they had obtained their growth, and subsequent rains having frequently stained the late picking."

Again: "*Florence, on the Chattahooche, Ga., October* 18, 1845.—Since

my last the prospect is better for the cotton crop in this section, and I am now of opinion we shall gather nearly a full crop in this county, as the several growths on the uplands have nearly all matured, and considerable of it opening at this time. We have not yet had a killing frost, and the weather is now fine for the growth of cotton. Our first picking here was not so good in quality, but the second is pretty cotton, and I think the quality will be as good as the average of the season."

"*Fine cotton.*—The Augusta Chronicle and Sentinel of the 31st ultimo says: 'A sale of 100 bales of cotton, a part of the crop of W. J. Eve, of this county, was sold on Wednesday, at eight cents per pound, and yesterday a lot of 48 bales of the crop of F. Merriwether, of Oglethorpe county, brought seven and three-fourths cents. They were both very choice lots, in square packages.'"

From other sources, it is stated that, in the central section, lying west of the Ocmulgee river, there has been about "three eighths of an average crop." Higher up it was better. In the northwestern corner of the State it is estimated that the crop was cut short at least "one-half." We believe that the average decrease of 20 to 25 per cent. will be a fairer estimate.

The prospect of the cotton crop in Alabama, in June, was decidedly good. It was considered fully a fortnight later, indeed, than the previous season. Somewhat nearer the close of the month the account from Mobile is stated to be, that insects and the disease known in the country as "sore-skin," rendered the appearance less promising in some of the counties. From other sections of the interior, however, the accounts are still favorable, and although the season has generally been admitted as two weeks later than last, it will be remarked that the first cotton blooms appeared a day or two earlier this season in our own State, and about a week sooner in Mississippi. On the 24th ult. full-blown blooms were seen in Warren county, in this State, and bolls as large as musket balls on the 1st inst. The early bloom of cotton is regarded by many as indicating a long season, or a late frost, and consequently a large crop. The numerous casualties, however, to which this plant is exposed, and the long period yet to elapse before the crop can be considered made, should admonish us of the futility of speculating on the subject for months to come."

In July, we learn—"The cotton is suffering from lice in consequence of the unseasonable weather. A fine rain and warmer mornings would brighten the prospects of the coming crop considerably."

Again, the Mobile Journal says: "We still hear complaints of injury to the cotton crop from continued drought; but probably, ere this, those sections of the country have been visited with a sufficiency of rain to revivify the drooping plant. Correspondents from the interior begin to be apprehensive of a greater injury from the excess of rain from this time till the close of the season. In Marion county, Alabama, the cotton crop had commenced falling, but could wait longer for rain without much injury. The growth is not so large as last year at this time, and, unless we have too much rain in August, will yield an average crop. The River State Review, of the same place, of the 9th instant, says: We have had but very little rain, but the cotton crop is not injured, but very promising."

So, in August. Extract of a letter dated Montgomery, Alabama, August 14: "Our corn and cotton crops will be very short in this section this season, in consequence of the long drought we have had. New cotton begins to come in freely. Prices range from 6 to 7 cents."—*Nat. Intelligencer.*

Again, in the New York Farmer: "*Alabama.*—The cotton crop will

probably be good, as there have been no complaints of an excess of wet to injure it. We expect a fair crop."

In a letter from Montgomery, of August 20, a writer says: "From the best information that we can gain of the incoming crop of this part of the State, and indeed of the State at large, it must be a very short one. The frosts in the spring, the 'lice' a little later, and the lack of any thing like a season since March or April, together with the appearance of the plantations, so far as they have fallen under our observation, all convince us that the present crop will fall far below any preceding one for the last five, or even ten years."

Again: "*Cotton crop of East Alabama.*—The crop in Barbour, Russell, Tallapoosa, Chambers, and Randolph is pronounced a failure. The Wetumpka Whig of the 28th says: In Barbour the crop is very short, but we have heard no estimate of the probable deficiency. Russell, Tallapoosa, and Randolph, lack a full third of an average crop, and Chambers nearly one-half. Benton, we are informed, will make nearly an average crop. They suffered very little there from drought. In Chambers we conversed with a number of farmers, not one of whom had made a half crop. One has got four and another six bales from 50 acres of land each, such as usually produces from 600 to 800 lbs. to the acre. Another planter assured us that on no part of 300 acres in cotton would he gather more than 250 lbs."

The Mobile Reporter, of August 26, also represents the crop as falling short of the average.

Subsequent information is of the same general cast. In the southeastern section of the State, it is judged to have fallen off "one-fourth." In the central section, "one-third." "The drought injured it. It appeared to revive in the early part of the fall. The frost, however, nearly destroyed the newly formed bolls." In the western part of the State it was about "20 per cent. less." Taking the whole State, the decrease was probably from 15 to 20 per cent.

Mississippi furnishes a large amount of cotton. The lands having been more recently devoted to this purpose than those of the cotton-growing Atlantic States, they are still in their vigor, and will probably be so for a number of years to come. Some complaint is made of the crop suffering from the lice; but on the whole it is believed to have been a fair crop, and in some portions an increased one.

The accounts we have gathered respecting its progress have the usual diversity. In June, the Clarion, of Paulding, speaking of this crop, mentions the ravages of the lice, by which the cotton in that vicinity had suffered. The following notices are in the same month. The Jackson Southern Reformer (Mississippi) says: "We are sorry to learn from various portions of our State that the cotton crop has been greatly injured by lice. In several parts of Yazoo and Madison, planters have lost three-fourths of their present stand. We also learn that in counties to the east similar damage has been sustained. Such has been the case in Lauderdale, Kemper, Neshoba, Noxubee, and several other counties."

"The Yazoo (Mississippi) Banner, of the 21st, states that the crops in that county are unusually promising. The Macon (Noxubee county) Independent, of the 19th, says the cotton crop was never more promising; and notwithstanding the usual proportion was not planted, yet we anticipate an abundant crop."

In July. The Carrollton Democrat, of the 23d ultimo, says: "From diligent inquiries, we learn that the cotton in this section of country is unu-

sually promising; and if the picking season is favorable, a larger crop will be gathered than for several years past."

A statement early in July from M. W. Phillips, contained in the Southwestern Farmer, gives the following view of this crop at an earlier date: "The cotton crop is, generally, 10 to 14 days more backward than last year. Of this crop we will give more than this passing notice, it being one of importance to the world. The stands of cotton, when first rising, were the best we ever saw; and we have heard the same expression everywhere we have been. At present, this is not so. Much injury has been sustained by the cut-worm and the cotton louse; some planters have been compelled to replant very largely since the 25th of May. We saw some cotton that had just risen on the 7th of June. In some regions on particular plantations, and in spots, the stand has been totally destroyed, whether planted on cotton, or corn, or stubble land—on ridge, level, or in hollows. It seems as if these pests would destroy on different descriptions of land on different places. We are not sure but that these pests may benefit some by thinning; but when they have destroyed, as on James Brown's plantation, for instance, the crop must inevitably be shortened; though a favorable fall effects wonders in a cotton crop. Although the first bloom on some farms would only indicate eight to ten days' backwardness, yet the general crop wherever we have examined, except four or five plantations, shows clearly at least two weeks. To explain: The first bloom we saw was on the 7th, at Mr. Low's plantation, between Livingston and Canton—off the road. The first that was seen there last year was on the 28th of May—only ten days difference. But last year, by the 7th the crop would have averaged five to ten forms; this year, not a stalk in ten has a form. Again, on many farms there are stalks that will measure two feet, and far more that will measure under six inches; irregular in height; much now dying from the effects of the louse; cut-worms are even now cutting off the cotton, even six or eight inches above the ground. A few have increased their cotton crop; some have decreased. A few have gone to the coast to raise sugar, and probably a few have quit cotton; we know of one, and heard of another. Taking all this together, we place the crop as last year, as to quantity cultivated. If we sum up the whole *pros* and *cons*, taking into consideration the unfavorable season, with the backwardness of cleaning the crops, we do not think the cotton crop will be as good generally on the 20th of June as it was last year from the first to the fifth. No human being can prognosticate thus early; but we may each one count on not making what we did last year."

The Planters' Banner of the 20th September likewise furnishes information from the same writer, still later: "Dr. M. W. Phillips, of Hinds county, Mississippi, writes us as follows, under date of the 7th instant: 'I have made inquiry as to the present crop. But few planters can be induced to give an opinion. One planter, who has made short crops for several years—letting his negroes manage themselves—told me last night that he and four other neighbors, together, would not make what he made last year—125 bales. They ought to make four times as much. Those who will express an opinion, think that the crop of this county and Madison will not exceed half a crop. Last year I had 93 acres in, and sold 81 bales; this year I have 105 in, and will thank any one prodigiously to insure me 70 bales. I will be 20 bales short of the average yield. This shows enough deficit; which, if general, and no greater loss, will be equivalent to a re-

duction of 300,000 bales. This subtracted from last year's crop, adding the supposed loss by overflow, will make the present crop less than 2,300,000 bales. Will it exceed 2,000,000 ?' "

The following is of a later date; it appears in the Savannah Republican of October 31: "We are indebted to friends in this city for the following extracts of letters in relation to the crop. Up to this time there has not been a killing frost in this State, and the weather is now unusually warm and very favorable for maturing the plant.

'*Holly Springs, Miss., October* 18, 1845.—Since the early part of September the weather has continued dry and very favorable for picking as well as maturing the young bolls of cotton; and the planters having made good use of the time, have already picked out a great deal more than they expected to make a few weeks ago. From all the information I have—and my business and situation enable me to hear from every part of northern Mississippi—we shall make the largest crop of cotton that has ever been made in this State. In several of the river counties the planters are making 2,000 and 2,500 pounds to the acre; and I think the average product in most of the counties in this region will be 1,000 pounds to the acre. A bale to the acre is very common on the valley lands. The quality is also very fine, having been picked without any rain.' "

The information obtained still later is of considerable diversity. In parts of the State there has been an increase; in others, a falling off. In the southwestern portion, for example, lying west of the Pearl river and south of the Yazoo river, the increase is thought to have been "5 to 10 per cent." There was an increased cultivation in the northern portion of the State, though the amount per acre may not have exceeded if it equalled the crop of 1844. On the whole, it is believed that the crop for the State was larger than in the previous year by 15 to 20 per cent. above the estimate for that year, which it would appear was too low.

The cotton crop of Louisiana was, we think, better than that of the previous year. The drought affected it considerably, early in the season, and some complaints are made of insects. But the long period of dry weather enabled the planters to get out the grass from among the cotton, so that the evil was in a measure counterbalanced.

In July, the Natchitoches Chronicle of the 5th says: "From all parts we hear favorable accounts of the crops. The rust, which made its appearance in some cotton fields a few weeks since, has done little injury and disappeared."

Other notices in August read in this manner: "The crops in the parishes of East and West Baton Rouge, says the Gazette of the 9th instant, have not generally, for several years, presented as promising an appearance as they do at present. The planters of Point Coupée are busily engaged in picking their cotton. The staple is represented to be generally of a fine texture."—*New Orleans Picayune.*

"The cotton crop has suffered very much; and now that the picking has commenced, planters are beginning to see better the damage that has been done by the falling off of the forms, and otherwise. A friend, who has been travelling over this and a number of the neighboring parishes, informs us that the hopes entertained by the planters a fortnight ago it is now certain will not be realized."—*Concordia Intelligencer.*

Subsequently, in September, &c., complaint is made in some parts of frost and rains. The Saint Landry (La.) Whig, of the 8th instant, says: "For

two weeks past we have had rain every day; sometimes in perfect floods; at others, in but gentle showers. The consequence is, cotton is suffering very considerably. We thought it advisable to say nothing of these rains last week, hoping they would abate, and enable us to assure our friends that the damage was but small; yet it is otherwise. Our prospect in the beginning of the season was most propitious; but if we say now that at least one-fourth of the crop will be lost, from the rain and rust, we certainly are below the actual mark. These are lamentable truths, which it gives us pain to chronicle."

Again: "The frosts that occurred during the early part of last week have been sufficient to check effectually the growth of cotton on the low lands. The calculation is, then, certain, that bolls of the blossoms of the 15th September cannot make, or rather mature."—*Concordia* (*La.*) *Intel.*

"The Clinton brought down 1,420 bales of cotton. The Monarch brought 1,808 bales. The Sultana 2,764 bales, the largest load yet. Making 6,092 bales on three boats, arriving within an hour or two of one another."—*New Orleans Tropic, October* 27.

Again: "The cotton planters have had most favorable weather for picking, and we hear no more of a short crop. It will not, however, be much; possibly no larger than that of last season. Prices range from 6½ to 8½ cents."

The information since obtained speaks of an increase of 10 per cent. more, in consequence of the overflow which was caused by the crevasse of the last year, (1844.) There was more cultivated, and the general crops of the alluvial lands were rather heavier, in consequence of the dry weather, and the decrease of the cotton crop in the upland by reason of the drought. On the whole, it is believed it will average 10 per cent. more.

The same was probably the case in Arkansas, if the ratio was not even larger, on account of more land being brought under cultivation. It is believed, however, that any increase in this way may have been balanced by the emigration further west.

Florida, since it has been open to cultivation by the resettlement of the country on account of peace, has gained in her crops of all kinds; and her cotton has increased probably 20 to 25 per cent., as it lies so much further south.

In July, it is said, in one of the public journals: "We hear that a good crop of cotton is expected. The Floridian of the 5th instant says: 'We were presented yesterday with an open boll of new cotton picked on the 1st. The staple is fine and beautiful, and would rival the snow in whiteness. We believe this to be the first boll of cotton that has been picked in this county this season.'"

Again: "The cultivation of this valuable staple seems destined no longer to be confined to the limited section of country that has hitherto produced it. Several attempts have been made to extend its cultivation in other places; and many of these attempts have proved quite successful. The Tallahassee Floridian states that five or six samples of cotton, raised in Middle Florida, were lately exhibited in that place; and after being examined by competent judges, were pronounced to be worth from 22 to 30 cents per pound. The best specimen was raised on light, sandy soil, which would produce about 325 pounds to the acre. Two of the samples, grown on pine land, would yield about the same quantity. Another sample, grown on red clay soil, was equally good; and, altogether, the experiments were quite encouraging."

The Tennessee crop was better than an average. As early as June it is stated that an average crop may be expected. The Nashville Union, also, yet later, states, that in that section of the country the stand of cotton is finer than they ever saw it before; though fears had been entertained by some that the late frosts had injured the cotton crop.

The Texas crop is much larger than it ever was before, and is believed, on the whole, to have been 50,000,000 pounds.

On a review of the whole cotton-growing region, it is believed, therefore, that although the crop has fallen off in the Atlantic States, on account of the drought and the emigration to the richer cotton lands in the States further west, yet the increase in the southwestern States and Texas has more than made up for it. We have based our calculations on the fact that the estimate for 1844 was not large enough, and calculated the increase or decrease accordingly. This should be borne in mind in comparing the estimates of the two years. In the Baltimore Sun of October 14 we find the following statement, which relates to the whole crop. It will be seen that the estimate does not vary essentially from the one we have made:

General Jesse Speight, of Mississippi, a cotton planter of much experience, gives it as his opinion, in a communication to the Columbus Democrat, that the present cotton crop will not much exceed 2,000,000 bales. He writes the communication from having seen, in the Albany Argus, a statement to the effect that the crop would prove to be a heavy one; amounting to 2,500,000 bales."

We add, also, a few notices of some remarkable varieties of cotton, &c., which we have taken from the public journals.

" Mr. R. P. Burton, of Camden county, has sent us a cotton stalk grown upon his plantation, which, in its line, beats anything we have ever known in these parts. It is of the fine *big cream* kind, and is nearly 12 feet high, and about *ten* feet [probably meant for two] in circumference at the foot of the stem. We learn, from the letter accompanying it, that the number of bolls and forms contained upon two limbs, each six feet from the ground, amounted to seventy-eight. The whole stock contains several hundreds—too numerous to count. But what is most remarkable, it grew upon land which had been *planted in succession eleven years*. It would be a curiosity at any time; but, for so dry a season as the past has been, it quite takes the rag from every other bush. We intend to have a cane made from the upper portion of the stalk, if we can find enough of sufficiently moderate dimensions for the purpose."—*Savannah Republican.*

The Cassville (Geo.) Pioneer says: " Mr. Hugh F. Longing, living in Henry county, on the Towaliga, eight miles from Griffin, brought to our office last week a stalk of cotton, which he calls the New Orleans and money-bush cotton, which he stated grew on second quality uplands, now 20 years in cultivation without manure. The bush was literally covered with pods. He said he should gather from the field planted at the rate of 1,500 pounds to the acre; while a patch of the common kind along side of it, on the same soil, with the same attendance, would not produce more than 1,600 pounds to the acre. His brother last year planted, in Harris county, fourteen acres of the same kind of cotton, on second quality gray post-oak land, and gathered from 2,000 to 2,500 pounds per acre."

Dr. Cloud, of Alabama, says, in a letter in the Cultivator of March, 1845, respecting a sample of a variety of East India cotton: " The stalk from

which this sample of cotton was taken attained the height of 13½ feet; had on it at frost 60 bearing limbs, and measured 16 inches in circumference between the first two limbs from the ground, and contained at one time, about the 1st of September, upwards of 1,200 bolls, blooms, and squares. My opinion is, that this variety promises to make a great produce in our climate. When other cotton was selling at 4½ cents per pound, I was offered 15 cents per pound for a sample of this. It is the true green seed—the natural tendency of our climate and soil—and therefore the kind upon which our improvements should be made."

The following paragraph is interesting:

"*Analysis of seed cotton—as a farmer, not as a chemist.*—I have, as is my usual custom, weighed and ginned out a lot of cotton, and give the result of the analysis. The loss of 13 pounds I am unable to account for, knowing that accuracy and care were observed, for I weighed every parcel and ginned it myself; for, where popular accuracy is required, I do all the work I can. Weight of seed cotton, 404½ pounds; weight of cotton seed, 274½; cotton, 113; motes, 3; loss, 13; total, 404½. The seed measured, heaping measure, 11 bushels. The seed weighed, per bushel, 25 pounds. It thus requires 1,410 pounds of dry cotton to make a bale of 400 pounds, exclusive of baling and rope; which contains 35 bushels of seed, and yields the small average of 28 pounds per cwt."—*Southwestern Farmer.*

In the appendix No. 11 will be found several interesting articles, &c., relating to the culture of cotton. One of these is from the Southwestern Farmer, and contains Governor Hammond's report on the culture of cotton, with the comments of the editor of the journal—supposed to be M. W. Phillips. Mr. McDonald's mode of preparing cotton for the market will also be read with interest by cotton planters in the south. In another of the articles is a letter from the "*Union*," containing an account of the failure of the cotton experiment in the East Indies by the British government. On the other hand, we have also given some statements of the views indulged on the other side of the Atlantic respecting the same object. We pretend not to reconcile the apparent contradictions, but give them only as a part of the history of this effort, on the part of the British nation, to render themselves independent of our supply—a fact which does not seem to be near at hand.

An article in the Foreign Quarterly Review of July, 1845, deserves also some notice, on account of the development of plans suggested to aid this movement. The subject discussed is "Railways in India." The writer says: "Among these, if we commence operations with the Deccan, the most important by far will be cotton, of which a sufficient quantity may speedily be raised in India to render us completely independent of the slave States of America. And here we may briefly allude to a fact, which will not be regarded with indifference by the friends of humanity: A company has just been established in London expressly for the purpose of promoting the cultivation of cotton in India; primarily with a view of combatting slavery, by depriving it of the aliment on which it feeds. But, in whatever motive such an association may have originated, its results cannot fail to prove beneficial to commerce. Recently, great efforts have been made to improve the quality of cotton in the collectorate of Poonah. In one district an extremely fine sort, equal to the best Baroche, has been introduced, and fetches a very high price at Bombay. In other parts arrangements are making for cultivating the New Orleans cotton, which the

most experienced agriculturists in western India expect will thrive admirably. It will be comparatively of little avail, however, to expend money on the great cotton grounds of India, unless, at the same time, we provide the means of conveying the produce of those grounds on the coast. This consideration chiefly, perhaps, has suggested to Mr. J. Chapman, a man of remarkable abilities and extensively acquainted with the country, the propriety of running the first line of railway across the Deccan, from Bombay on one side to Coriuga on the other. The line would commence at Bombay—run along a causeway to the island of Salsette—reach the main land by means of a bridge thrown over what is called the Tannah river; and then, traversing the Cocan, ascend the slope of the Ghauts—pass by Poonah, a city of 130,000 inhabitants, and, diverging towards the north, cross the district of Ahmednugger; sending out branches to Shulapore on the one hand, and Patoda on the other. From Ahmednugger, following the great valley of the Godavery, it would project itself eastward, till, through the Bheer cicars, it entered the Nizam's dominions. Proceeding across Nundeer, and sending forth an important branch northward to Oomrawutty and Nagpore, which might ultimately be carried over the Nerbudda to Allahabad, it would intersect the cicar of Eilgundel; whence it is proposed that a branch should be carried southward to Hyderabad, the Nizam's capital—a city larger than Paris, and containing 800,000 inhabitants. It is intended that this branch line shall afterwards be carried across the Kisna to Madras, from which port it is calculated that 134,000 tons of merchandise are now annually shipped. From Eilgundel the trunk line would stretch through Tullangoar, Warangal, Kummumet, and Rajahmundry, to Coriuga, probably crossing the Godavery where its channel is intersected by numerous islands. Thence the railroad would be carried through the northern cicars and the province of Orissa, to Calcutta. Among the advantages of this line, there are some few which appear to be deserving of especial notice. Upon the first and greatest we have already touched—we mean, that it would intersect the cotton districts; but there are several others which ought not to be overlooked." The writer elsewhere goes into the cost of transporting cotton to the coast. The cost of transport from Bellary to Kamptee, in Camara, 184 miles, has been reduced, by having a cart road, from 7¾d. per ton per mile to 3½d. The writer goes on to say: "This cotton, ill-cleaned and subject to much damage from thorns and bushes on the road side, and dust during its passage, on the backs of oxen, below the Ghants, sells at Kamptee for little more than twopence per pound. Thence it is shipped for Bombay, where it is screwed into bales for the English market. It has been found, upon calculation, that the cost of bringing this cotton from Bellary to Kamptee, a distance of 184 miles, considerably exceeds that of conveying it to England, a distance of 17,000 miles. Taking the price of carriage in India at 2½ annas per ton per mile, and reckoning the value of money according to the price of bread-corn—at six times what it is in England—it is equal to 22½ pence there; whereas the expense in England is 10 pence per ton on common roads, and about 3 pence per ton on canals in general, or even as low as one penny. If 3 pence be the average, it is less than one seventh of the cost in India. The expense of the transport of goods from Madras to Trichinopoly, 230 miles, is 25 rupees, or £3 10s. per ton, which is nearly as much as the freight from Madras to London. The most important fact, however, still remains to be considered. When brought into the market at Liverpool, this cotton often

sells with difficulty at 3 pence per pound, so that the merchant importing it profits but very little by the transaction."

Several interesting tables, as well as extracts from the Liverpool Times, giving a full view of the cotton trade of Great Britain for the past year, will be found included in appendix No. 11.

By this, it appears that while the product of the United States imported into Great Britain has increased from 1,157,924 to 1,376,894 bales, that of the East Indies has fallen off from 142,796 bales to 79,640 bales; and that of Demarara and West Indies, &c., from 14,674 to 6,314 bales, and Brazil and Portugal from 112,369 to 110,176 bales. The Mediterranean only, besides the United States, has increased, viz: from 63,221 to 79,707 bales. The whole increase of import is stated at over 174,000 bales.

The prospect seems to be that an increased market for cotton may be opened in Russia and Austria, and perhaps some others of the European kingdoms. Such is a view of an intelligent traveller in the latter empire; and as to the former, see the following extract, found in one of our public journals:

Extract from a letter from A. P. Gibson, esq., United States consul at St. Petersburg, dated August 30, 1845: "The quantity of cotton imported this year direct from the United States is 6,992,818 pounds, whereas the highest import heretofore was 3,150,680 pounds in 1843. If this government should not change their present policy in respect to their encouragement of manufacturing establishments, Russia will become a great consumer of raw cotton, for the number of spinning establishments is constantly on the increase; and it is estimated, by competent judges, that by the end of this year there will be in operation in the whole empire from 800,000 to 1,000,000 of spindles."

The progress of cotton to its manufacture, and its increased value, is curious. A statement is given in the public journals, which thus traces it when sent to Europe:

"*Progress of a pound of American cotton.*—The following is the history of the travels and adventures of a pound of manufactured American cotton: The cotton came from the United States to London; thence to Manchester, where it was spun into yarn. It was then sent to Paisley, where it was woven; next to Ayershire, to be tamboured; afterwards it was conveyed to Dumbarton, where it was hand-sewed. It was then again sent to Paisley, when it was conveyed to a distant part of Renfrew to be bleached, and then returned to Paisley. It was afterwards sent to Glasgow and finished; and from Glasgow it was conveyed, per coach, to London. From its shipment in America till its arrival in the London warehouse, it must have been conveyed 3,000 miles by sea, and 920 on land. The value was increased 2,000 per cent. by the processes of the manufacturer, whilst no less than 150 people were engaged in its carriage and preparation."

The subject of cotton mattresses was mentioned in the report for 1844. Since then, we have found it stated that they are extensively used, and preferred to all others, except hair mattresses, on board of many of the steamboats at the west. A further testimony in their favor, we learn, is also given in the Boston Medical and Surgical Journal, an account of which is thus given in one of the public journals. "The Boston Medical and Surgical Journal, in an article from Dr. Smith, says that a great business is doing there in cotton mattresses. There is in the city of Lowell an extensive manufacture of these beds of an elegant appearance. They have the ex-

ternal finish of hair mattresses; but, besides being equal to any material in use for stuffing a tick, they have an important advantage over all other kinds of beds known to the community in their cheapness. They do not, it is said, seem to differ essentially in point of reaction, after being laid upon, from hair. For economy, they put even shaved ratan at defiance. In winter, it is a non-conductor of caloric. On board of ships and steamers, besides fulfilling the first intention of furnishing a first-rate sleeping apparatus, each one would become a life-buoy in case of emergency, capable of bearing up a man. In hospitals, especially, in which bedding is always a great annual outlay—arising from the fact that a great many beds are necessarily destroyed in consequence of imbibing offensive discharges, &c.—these cotton beds will speedily, we apprehend, become an important consideration. Feathers have been rapidly passing out of fashion for years; yet hair is too dear for universal use, a large part of it being imported. Cotton is a product of our own country, to be had in any abundance. The only question in our mind is as to the healthiness of the article; but, as we have the recommendation of a good physician and an able medical journal, we suppose the objection is rather one to be put down to prejudice than to fact."

RICE.

The rice crop is nearly all raised in the two States of South Carolina and Georgia. The last year's crop, (1844,) it will be recollected, was considered to have been unusually fine. The intelligence respecting this crop the past season leads us to conclude that it was not as large as the usual average one. We give a number of statements from notices in July, on which this conclusion seems to be authorized.

" *Georgetown, S. C., July* 12.—We have had four refreshing rains during the week, which will do much service to the upland crops. But the rivers continue salt, and the rice planters who planted the 1st of April are much annoyed with worms and flies, being unable to take on water, and find it unsafe to change that which was taken on when fresh. Some crops up the rivers look very well, and promise an early harvest. On Wednesday, Mr. Bates sent us three stalks of rice from Mr. Richard O. Anderson's Ramsey Grove plantation, full five feet high, one of which had put out a fair ear, and the heads of the others were visible.

" The annexed letter is from an experienced planter in the neighborhood, and the information it contains may be relied on as to the Black river and Pee Dee, and indeed the whole rice district:

' Black River, *July* 10, 1845.

' Dear Sir: A friend of mine, who resides on the Pee Dee river, six miles by water from Georgetown, brought me a pint bottle of water taken from the Pee Dee river, at high water, on Sunday. On Tuesday I had the same bottle filled at high water, in the vicinity of Pringle's ferry. The contents of both were boiled separately, and produced one teaspoonful each of salt. The water from Black river produced rather more than the Pee Dee water. The water is sweet here at high water, and I look for salt the first easterly wind. Should this drought continue for one week longer, I have no doubt the salt will go very high up this river. The crops of rice, consequently, must be short. I estimate the loss at one-fourth at least, and particularly low on the rivers. The old rice is in barrel; (I have one field

ready to put out;) the second planting in joint, and the young rice wanting showers. The rice crop has also to contend with maggots, where the water cannot be used; and the dry rice has weevil and Hessian fly, both of which are very destructive. Amongst all these difficulties, I think my estimate of one-fourth as an average loss is within bounds.'"

Again: "The harvesting of the rice crop in this State was pretty generally commenced in the early part of last week; but, owing to the frequent showers, there has not been much progress made in securing it. We yesterday conversed with a gentleman, who, from his position, is perhaps better informed as to the rice crop in this State than any one else in the city; and he gives it as his opinion that on the Savannah there will be but little less raised than last year, notwithstanding the crops of several planters have been almost entirely destroyed by the salt water. On the Ogeechee there will be an increase over last year, provided the remainder of the season should prove favorable for harvesting. On the Altamaha the crop will be much less, and on the Satilla there will be a great falling off. On the inland plantations the crop will be light, owing to the extreme and long continued drought. On the whole, the crop in this State will be considerably short of that of last year, and prices will therefore rule correspondingly high. We are inclined to think, from all we have heard and read, that the crop of South Carolina will show a greater falling off than that of our own State. We may reasonably conclude, therefore, that the Savannah market, owing to the abundance of the production on this and the Ogeechee rivers, (most of which finds its way here,) will be found equal to that of any other."—*Savannah Republican.*

Again: The Georgetown South Carolina Observer of the 30th ultimo says: "The rice harvest has commenced in some parts of the district, and will be general in the course of the ensuing week. All our fears as to a short crop will be fully realized; and we put it down now as certain that the crop of this neighborhood will be short at least 10,000 tierces. This has been the most inauspicious year for the rice crop in the recollection of our oldest planters, owing altogether to the salt water, which, owing to the general drought of the last summer, ascended our rivers where heretofore it was not known. The potato crop is as good as usual, and so is the rice crop, high up the Pee Dee, Wackamaw, and Black rivers."

So, in August: The Wynyah Observer of the 17th instant says: "We had not supposed the injury so great as it turns out to be since the heading out of the rice. The crop is very short, and we shall be the better able to speak of it as the harvest may progress. Since our last there have been some heavy rains; and the fall of rain in the up country has given at last rain enough to allow many of the planters to flow with fresh water; but the season is too late to effect much good."

Still later: "The Savannah (Georgia) Republican gives the opinion, formed from the best sources of information, that the crop of rice in that State will be considerably short of last year, and that prices will rule correspondingly high; and that the crop of South Carolina will show a greater falling off than that of Georgia. The Wynyah Observer says that the fears of a short crop will be fully realized, and that it is certain that there will be at least 10,000 tierces less raised in that neighborhood than usual; that, in consequence of the drought, it has been the most inauspicious year for the rice crop in the recollection of the oldest planters."

The information otherwise obtained corresponds to the above, and the falling off is variously estimated at from 25 per cent. to one-third, as compared with the crop of 1844. In Alabama the decrease was probably not quite so large, and perhaps the same remark should be applied to the crop of Louisiana; but the whole crop is undoubtedly less than that of the previous year.

The whole rice crop, according to the estimate, is 89,765,000 lbs., which is about one-fifth less than the crop of the preceding year.

In the Journal of Commerce we find mention of a *wild rice*, which is stated, by a correspondent of that journal, to abound in the northwestern part of our country. He says: "In noticing the plants of interest in the country through which I have travelled, that of the wild rice presents an interesting appearance. It is everywhere found on the upper lakes, and, as is well known, constitutes an important article of food with the Indians. We found it growing extensively along the borders of the lake St. Croix, and skirting for a considerable distance the shore of the river. It was in full bloom. The seed part of the plant appeared at the very top of the stalk, while the blooms or pollen were attached to the stalk below the seed head. It appeared to be very slightly attached to the marshy deposite at the bottom of the lake, by its roots being easily pulled up. The entire length of a stalk is four or five feet, with one-half of it beneath the water. Its blades, stalk, and head rise from one to one and a half and two feet above the water. It grows so thick, that when viewed at a short distance it presents a uniform surface of green, entirely concealing the water beneath. It ripens in September and October, when it is gathered by the Indians, who go among it in canoes to obtain it. Its blades are tender and sweet tasted, and would no doubt make very nutritious fodder for cattle. Why could not this rice be sown and raised along the shores of the fresh-water lakes of western New York, and in the New England States? Its grain would be found useful for a great many purposes, and especially for poultry. Immense numbers of wild ducks and other wild fowls flock to the rice fields of the lakes in the autumn."

Another correspondent of the same journal remarks on the above: "The account given of the wild rice of the great lakes, by your correspondent (Putnam) is very interesting. I have about a pint of the grains of the wild rice, which in 1844 I brought from Rice lake, which is the head of the river Trent, in Upper Canada. This rice was gathered by the Ontonabee Indians. The Indians run bark canoes into the aquatic grain fields, and with a long pole turn the rice heads over the side of the canoe, and then with a stick beat the grain out of the heads into the canoe. The grain is of a dark olive color, and is from one-half to three-fourths of an inch in length. I ate of it, when at Rice lake, at the house of a friend, who purchased it every year from the Indians. It was boiled and served up as a dessert, with fresh butter and the sweet sirup of the maple tree; and, thus prepared, was not inferior to the best southern rice. I sent a few kernels of it to the Farmers' Club of the American Institute, in May last, to be distributed. The plant in Rice lake, in some places, grows in 12 feet water. It requires what is termed a rich black mud to take root in. I expect to receive some more of this rice in about ten days, from Rice lake."

In the New Farmers' Journal, an English periodical, mention also is made of a new species, lately brought to view at Sierra Leone, called the Fundi rice, or sometimes the hungry rice. It may, perhaps, deserve atten-

tion from the planters in our southern States. It would seem to be an upland rice, from the description which we subjoin:

"*New species of rice.*—Mr. R. Clarke, the senior assistant surgeon to the colony of Sierra Leone, has lately brought into notice a grain called fundi, or fundungi, cultivated by industrious individuals of the Soosoo, Foulah, Bassa, and Joloff nations, by whom it is called hungry rice. It is a semi-transparent cardiform grain, about the size of a mignionette seed; the ear consists of two conjugate spikes, the grain being arranged on the outer edge of the spike. The ground, says Mr. Clarke, is cleared for its reception by burning down the copse wood, and hoeing between the stumps. It is sown in May or June, the ground being lightly drawn together over the seed with a hoe. In August, when it shoots up, it is carefully weeded. It ripens in September, growing to the height of about eighteen inches, and its stems, which are very slender, are then bent to the earth by the mere weight of the grain. When cut down it is tied up in small sheaves, and placed in a dry situation within the hut; for, if allowed to remain on the ground and become wet, the grains become agglutinated to their coverings. The grain is trodden out with the feet, and is then dried in the sun to allow of the more easy removal of the chaff in the process of pounding, which is done in wooden mortars. It is afterwards winnowed with a kind of cane fanner, on mats. In preparing this delicious grain for food, it is first put into boiling water, in which it is boiled for a few minutes; the water is then poured off, and the Foulahs, Joloffs, &c., add to it palm oil, butter, or milk; but the Europeans and negroes connected with the colony prepare it as follows: To the grain, cooked as above mentioned, fowl, fish, or mutton, with a small piece of salt pork for the sake of flavor, is added; the whole being stewed in a close saucepan. This makes a very good dish; and thus prepard, resembles 'kouskous.' The grain is sometimes made into puddings, with the usual condiments, and eaten either hot or cold, with milk. By the few natives of Scotland in the colony, it is dressed as milk porridge. This grain could be raised in sufficient quantities to become an article of commerce, and I have no doubt would prove a valuable addition to the list of light farinaceous articles of food in use among the delicate or convalescent. Before preparation, the grain is said to be of a clear dull brown color, and when cleaned from the husks it resembles very fine millet."—*New Farmers' Journal.*

SILK.

The subject of silk culture is one which does not excite that general interest in our country which it may hereafter be destined to enlist, and which its importance might seem to render proper. There are a number of reasons which may be assigned for this.

A severe check was given to its progress some years since by the unfortunate *multicaulis* speculation. Many who suffered from engaging in that enterprise with too hasty a zeal, have not recovered from the timidity which the issue in disappointment of their sanguine hopes inspired; and others, who have learned of the loss of their neighbors, have been as averse as they to engage in new experiments. Yet, even that result is due rather to the period in which it took place, than to any thing in the nature of the subject. At a time when the public mind was not directed, as it then was, to all sorts of speculations, the multicaulis might have been successful;

though it is to be questioned if the climate at the north is adapted to it, in many parts of the country where the cultivation was attempted.

Another reason for the want of success in the general diffusion of the silk culture, is the absorbing interest which has been felt (in those sections of the country where it might best be tried) in some other crop. This is peculiarly the case as regards the southern sections of our republic; the climate of which is so well adapted to silk culture. Still, we believe that there is a gradual advance on the subject. Comparatively little information on the topic is to be obtained except in those papers which are more specially devoted to it, and there are but few journals which even give a column to it. Our information on the silk culture the past season is mainly derived from the New York Farmer and Mechanic. From the collection of articles on the subject there, we have condensed and present here, and in appendix No. 12, such statements as may best subserve our object at this time. The reports which we have received from the different parts of the country are so few and so meagre that we are unable to give any thing but a general view, without entering into much detail as to particular States. It is stated that there is three times as much raw silk manufactured now as there was three years ago, and that it is worth 50 to 75 cents per pound more than Smyrna silk. The specimens submitted at the last fair of the American Institute in New York were such as would compete successfully with the French and Italian silks. The frosts of last winter proved too severe for many mulberry trees in the northern States; and the Broussa, which seems adapted to cold weather, is recommended as adapted to these sections of our country. Five States—Maine, Massachusetts, New York, Delaware, and Louisiana—give bounties on silk. That of New York is about to expire. We have subjoined in the appendix the memorial to the legislature of that State for its renewal; also, the act recently passed in Louisiana for the purpose of aiding the silk culture there. A number of interesting communications from gentlemen at the south relating to this enterprise, taken from various journals, will also be found in the appendix. The following extracts are taken from the Planters' Banner of February 23, 1845: "To give the agricultural editors at the north an idea of our Louisiana climate, we would state that a lot of multicaulis trees in our garden have been in leaf for three or four weeks, and for the last few days we have been feeding silk-worms! Peach trees are now (February 22) in blossom, and most of the trees in this region begin to put forth leaves."

Again:

"*State Legislature*.—We learn from the Bee that the bill has passed the House of Representatives to encourage the culture of silk in Louisiana. Mr. Gaudet, who introduced the bill, appeared in the Hall of Representatives clad in a handsome dress coat made of silk grown on his own plantation."

Again:

"*Louisiana silk*.—Few have a notion of the various kinds of handicraft that is carried on in a small way in those parts of the city where the emigrants from continental Europe principally reside. Chance brought us into the house of a Belgian yesterday, and we found him engaged in weaving American silk (which he had spun himself) into shawls for ladies."—*New Orleans Picayune.*

Mention is made of various experiments in the manufacture of silk fabrics in different parts of the country. Those of Northampton, Massachusetts,

Paterson, New Jersey, and Mr. Gill's, in Ohio, seem to be among the most successful. "At Paterson they employ about 540 spindles for winding, 240 spindles for cleaning, and 1,000 spindles for spinning; 16 looms in operation for weaving, and are increasing their number; also 100 hands, mostly women and children. Some fancy-colored cravats and dresses were woven for a French gentleman of silk of his own raising, which the manufacturers pronounced equal to the finest Italian silk."

The silk statistics of Northampton, according to Dr. Stebbins, of that place, are—"three silk manufactories, with a capital of $14,000, employing ten males and forty-seven females; 75 to 100 pounds of American silk, worth $500; over 6,000 pounds of sewing silk and twist, worth $41,500."

The following is a specimen of the frequent notices which meet the eye on this subject: "*Figured silk ribbon factory.*—We have seen several specimens of figured silk bindings, manufactured by Messrs. Vogel & Co., in this city. They furnish conclusive proof that those men can manufacture any desirable article of the kind. We understand that they are rapidly getting their machinery in order for manufacturing all kinds of figured ribbons and figured vestings, by a process unknown in Europe, and with increased rapidity."—*Bangor Whig.*

In the Ohio valley there is considerable silk raised. Indeed, it is said that not less than 50,000 bushels of cocoons are now annually raised there. Mr. Bliss, in his report to the Ohio legislature on this subject, recommends a course which would do much to extend its cultivation. It is, that every farmer should have his patch of mulberry trees, and make it a point to raise at least ten bushels of cocoons.

The history of silk culture of this country is divided, by some writers, into three epochs. The first period, from its first introduction, in 1623, to the close of the revolutionary war, in 1783, or for 160 years. The second epoch, from that time to the decisive knowledge of the multicaulis mulberry; or to July, 1830. The legislature of Connecticut, in 1783, granted a bounty on mulberry trees and raw silk. The efforts of Dr. Aspinwall and President Stiles were the principal cause of this movement. The consequence of the introduction of the mulberry tree more largely, through their exertions, has been, that Connecticut stands among the first in this culture at the present day. The third epoch commenced about 1830–'31. It remains to be seen how great the progress shall be; but it is hoped that our countrymen will before long awake more to the importance of its prospective bearing on our national resources, and engage in it vigorously, and also with true discrimination and prudence. For this purpose they should acquaint themselves, as far as practicable, with the experience of others, and the obstacles or aids to their success.

We have placed in the appendix several valuable papers, which have been drawn from valuable sources, on this subject, and they will repay the perusal. The history of the silk culture in Georgia, by the Rev. William H. Stevens, which we have taken from the Southern Cultivator, is an interesting piece of instruction to the planters of the south. We may also mention Mr. Douglas's, Mr. Crain's, and Judge Ernest's communications, and others, as well suited for the same object.

Dr. Stebbins's letters and reports, Mr. Green's, Mr. Clemens's letters, &c., also relate to the more northern culture. We may again, also, refer those who desire much practical information in a small compass, to the pamphlet,

published two or three years since, called the "Silk Question Settled," and from which copious extracts were made in a former report.

The writer in the journal on the pages of which we have been forced mainly to rely in our remarks on this subject, observes that "it is evident, from letters received at the first national silk convention, and other reliable sources of information, that several thousand tons of silk are now annually raised and manufactured in the United States." He thinks that, owing to the want of proper management of the worms after they have spun their thread and formed the cocoons, one-half probably is lost.

A great obstacle to more success, is *the imperfect manner in which the reeling is performed.* "Hundreds of families," he says, "who raise several bushels annually, work them up into sewings and other articles for their own or their neighbors' uses. These, finding their way to the country stores, injure the cause of silk production; for, being compared with foreign silks, produced by proper machinery, they are found defective. There is much also wasted by these methods, as reeling, doubling, and twisting (instead of being made, as they should be, three distinct operations) are often performed on a single machine." He urges a division of labor, as without it we cannot succeed.

Another difficulty suggested, is, that persons are often forced to *keep their cocoons too long*—until they are injured and lose half their value. He cautions persons against the use of heat in the destruction of the chrysalis. The fibres are thus made so tender that cocoons which might have yielded silk worth $6 per pound, will only yield that which is worth $3. Alcohol is recommended, as it leaves the cocoons in fine order for reeling. It is said that the Northampton factories are very particular on this subject. The cocoons must be spread out very thin to become well cured. Cocoons, it is stated, become comparatively valueless after the 1st December, as the gum is so dry and hard as to injure the silk. The Northampton factories make it a rule not to purchase after the 1st December.

R. B. Forbes, of Boston, who is said to be personally intimate with the Chinese climate, mentioned in the New York Farmers' Club that the climate in China, between the parallels of 30° and 40° north latitude, is the most decidedly favorable for silk, and that silk from these latitudes is 20 per cent. better than that from the lower latitudes there. It is a little remarkable that we find it elsewhere stated that the best silk in this country is from cocoons spun in Vermont. It is said to be larger and stronger than silk raised in any of the southern or western States. The Vermont silk, we are informed, brings a higher price at Paterson, New Jersey, than silk from any other State.

Open feeding is still recommended. Silk-worms are said to suffer more in sultry, close weather, than in cold. Ventilation is all important.

A species of worm among the Persians is said to produce eight successive crops in a year; and a writer in Florida, Thomas Douglass, of Macavies, thinks that it would be useful to introduce this species into that State. The leaf of the morus multicaulis, he states, affords good feed for worms there *at least* eight months, and sometimes nine and even ten months in the year. He is sanguine that Georgia lower country and Florida silk will be quoted in the prices current of Liverpool and Havre in 30 years, if not indeed sooner. His letter, which contains many interesting particulars, and deserves serious attention from the planters of the south, will be found, with other papers, in appendix No. 12.

Some very useful directions as to silk culture, also, will be found in an article from the New York Farmer, by Mr. A. C. Van Epps, to whom we are indebted for much information on the subject. His paper, styled "A Chapter for Silk-growers," compactly embodies his observations on the various topics of a *supply of perfect eggs ; provision of suitable foliage ; place for feeding ; destroying the chrysalis*, and *curing cocoons*. He believes that the hatching of the eggs may be retarded without in the least injuring the constitution of the worm. The failure he attributes to either the worms being placed too late in the ice, or to the warmth of spring or summer, or their not being wholly imbedded in the ice. He describes the feeding frames and ventilating cradles, &c., and a method of curing the cocoons, in so easy a manner that any one can understand it.

An interesting letter by S. A. Clemens, of North Granby, Connecticut, also from the journal before mentioned, furnishes many valuable remarks, which we commend to the attention of those who are investigating the subject with a view to successful experimenting. He recommends cultivating the mulberry tree in rows about 3½ feet apart, and as thick as they can stand in the rows. "The trees," he says, "are kept headed down by cutting off the shoots several times in the season, as they spring from the ground. The foliage is thus easily obtained, and probably more of it than if the trees were planted wider apart and suffered to form trunks. The multicaulis has been cultivated in this way with entire success."

Mr. Clemens approves of *feeding with the shoots*, and says that as the young shoots are taken others form in their places, which gives a fresh supply of tender foliage until late in the season, and so obviates the difficulty in making as good cocoons from late as from early feeding. He prefers the *peanut* variety of worm, though he says that some in his vicinity choose the mammoth sulphur, as the silk reels more easily, and, though the silk is coarser, it answers well for sewings. He speaks of Mr. O. D. Payne's reel, of Northampton, as the best one.

Mr. Payne himself has also a communication in the New York Farmer. He says that the Alpine mulberry is preferred there; it is the saccharine matter which nourishes the silk-worm, and much depends on the proportions which the different elements of the leaves bear to each other. The leaf of the Alpine mulberry is most nutrient; and the more nutrient the leaf is, the less leaves the worm has to consume, and consequently the less labor to perform, and therefore is less liable to fatigue, languor, or disease. The small silk-worm, or the 8th crop, is the best. This he pronounces to be a very superior species, furnishing very superior silk, and of a very fine texture. His reel, he states, possesses many advantages over every other reel, and that Mr. Valentine, an English silk manufacturer in that place, procures some of the silk reeled on it—which he considered superior to any other he had known for evenness, color, and finish—to send to England. He says that the Northampton Association have succeeded in lustre, smoothness, and fineness of texture, not surpassed by the best Italian.

Another writer, Mr. W. H. Benton, of Raymond, Mississippi, approves of *cut* leaves, from which Mr. Van Epps dissents, and could not consent to admit it as a substitute for open branch feeding.

Mention has been made in various public journals of a plant, called the silk plant, sent from Tripoli; and, in the Farmers' Library and Monthly Journal of Agriculture for July, there is a plate representing the same, by which it appears to be a species of the asclepias, or what is termed milk-

weed, or silkweed. We subjoin the letter of Mr. McCauly to Mr. Markoe describing it. It has, however, been since stated that the fibre will not answer the purpose for which it is suggested, as it resembles the fibre of our milkweed, which has been tried in the way unsuccessfully.

"*Silk Plant.*—The following letter from D. Smith McCauly, esq., our consul at Tripoli, to Francis Markoe, jr., the secretary of the National Institute, will be read with much interest. He transmitted it with some seed of the vegetable silk, which, in all probability, in our varied and wonderful soil and climate, will become a new article of commerce, and, like our cotton, a new and important source of wealth. Should it succeed, and become a great staple article like our cotton, what important consequences may we not expect to follow from its introduction:

U. S. Consulate, Tripoli,
December 28, 1844.

Sir: I herewith transmit to the Institute a small specimen of vegetable silk, raised from a few seed that I received from Lucca, Italy, which seed originally came from Syria. Without any instruction or knowledge of this plant, I sowed the seeds in pots, in the month of March last. In May and June they obtained the height of 6 to 8 inches, when I transplanted them into my garden, about 8 inches apart—much too near, as my experience proves. In the months of August and September they were in flower, and the pods commenced opening in October, the plants being from 6 to 8 feet high; and, though we have had the thermometer frequently as low as 42° Fahrenheit, and the apricot and pomegranate trees, with the vine, have all shed their leaves, yet there remain several pods on the silk plant which are still perfectly green, and show no signs of suffering or cold. This, with some other proofs of the plant being hardy, induces me to believe and hope that it might be successfully cultivated in all our cotton-growing States; and should it become a staple commodity, no doubt the inventive genius of our countrymen would soon discover the means of spinning it without the aid of the cotton fibre, which, I am told, they use in Syria to assist in spinning, their knowledge of the art not extending beyond the primitive distaff. The only information that I have acquired of this plant further than recounted above, is from the mouth of one of the "propaganda" established here, who has seen it growing in Syria, where, he tells me, it flourishes, and that the cultivation of a small field gives support to a family; that in the second and third years it is extremely productive. The plants grow to the height of 10 to 15 feet, and are generally separated from 8 to 10 feet from each other. I also forward you, by this occasion, the small quantity of seed of the plant which the limited number I have raised enables me to spare, with the hope of sending a greater quantity next year, should the climate of our southern States prove favorable to its culture, or should it be even otherwise interesting. I beg you will distribute these seeds amongst those gentlemen of our cotton-growing States who will take an interest in making an experiment of the cultivation.

Very respectfully, sir, your most obedient servant,

D. SMITH McCAULY."

SUGAR.

The crop of sugar in Louisiana, it is believed, will not prove so favorable as was anticipated. That of last year (1844) was better than was con-

jectured to be the case at the time the estimate in the report was made. Much is made after the latest period in which we can receive such information as we must rely on to form even a conjecture. There was unquestionably a large additional number of estates turned to the sugar business. Mr. Chapommier states, in the New Orleans Bee, that in 17 parishes there have been 367 cotton plantations thus changed; and he says even this does not comprehend all, for this notes only new mills; and there are numbers of small planters, besides, who resort to the mills of their neighbors. In other sections he learns of 25 to 30, and in another 200 more.

The early notices of the sugar crop are partly unfavorable. Thus, in May: "The crop of cane in the Lafourche parishes, we are informed, is not very good"—*Planters' Banner*, *May* 24.

On the other hand, also, May 24: "We have just returned from a ride extending about 100 miles through Attakapas and Opelousas. We took particular notice of the crops. The cane in St. Mary, St. Martin, Lafayette, and St. Landry, looks remarkably well."

The St. Landry Whig, of the 17th, states that "the sugar crop of that parish will amount the present season to 1,400 hogsheads, being an increase of 700 over the product of last year."

In June, we learn "the sugar crop promises well." The St. Landry Whig, of the 10th instant, represents the sugar crop in that parish and in Avoyelles as promising an abundant return to the planter. "Should the worm fail to visit them, the sugar crops will exceed those of any previous year."

Again, June 13: "Sugar-cane looks remarkably well, and we have no doubt will turn out handsomely." Again, the Baton Rouge Gazette, of June 28th, says: "The drought for some time past has dried up the sugar-cane." The Lafourche Gazette, still later, speaks of the kind of weather as favorable to the growth of sugar-cane. The following is dated Franklin, July 12: "Down to the present time, our sugar planters of Attakapas have had quite a favorable season. The crop of cane is now nearly all laid by. Some of our planters will probably plough late, which will retard the ripening of the cane. A worm, which threatened much damage, made its appearance in the cane last month, but the heavy rains appear to have arrested its progress."

In September, it is stated: "Valerien Martin, of the parish of Lafayette, Louisiana, has already commenced making sugar. His sample was that of a fair quality. He commenced the 20th of September, and says his whole crop is ready for milling." Again: "The last Franklin Banner says that the cane throughout Attakapas promises well. Many of our planters will be prepared to roll about the first of October."

Later in October the accounts are various. Thus the Planters' Banner, of the 4th, says: "The weather, we regret to say, is quite unfavorable, not only for the ripening of the cane, but for the making up or boiling of the sugar crop. It has rained the greater part of the week, and planters will not commence rolling quite as soon as we anticipated a few days since. Many, we regret to say, have not finished hauling wood, housing potatoes, or gathering corn, and much hay and fodder has been lost by neglect and wet weather. The object of all now is to commence rolling as soon as possible."

Again, the Baton Rouge Gazette, of the 18th, says: "Sugar making has commenced, and is going on briskly on the neighboring plantations. The

cane fields present a scene of activity. The prospects of sugar planters this year are very encouraging. The Donaldson Vigilant, of last Thursday, has the following: Several of the sugar planters of our parish and of the Lafourche have commenced 'grinding.' The yield thus far has not been large. The weather, however, is now propitious."

"The Louisiana Planters' Gazette, of the 25th ultimo, states that the sugar crop of the parish of Iberville will be a very short one."

In a letter from New Orleans to a public journal, dated October 31st, the writer says: "The prospects of the cane are not favorable. I believe the crop will not exceed 150,000 hogsheads, which is 50,000 short of last season. I ought to add, however, that my estimate is below that of others who are well informed on the subject, who estimate it at 175,000 to 180,000 hogsheads. The crop is two or three weeks behind last year, and unfortunately we have not yet had cool weather to ripen it, and a large majority of the planters have not yet commenced grinding; and even some of those who had begun have suspended again, as the cane gave such a miserable yield. Last year at this time 40,000 to 50,000 hogsheads were already in the draining houses, and of course out of harm's way; whereas now almost the entire crop is at the mercy of an early frost, and will certainly suffer more or less from it, as the grinding will run so late into winter."

Later, also: "The sugar planters are all now under full way in their grinding, and the last ten or fifteen days has been favorable weather. The complaints of bad yield are very general on the river plantations; the crop will be less than last season; the best informed estimate it at 150,000 to 175,000 hogsheads."

The Planters' Banner, of December 6th, speaks more unfavorably as the season advances: "As we predicted, last week's rain was succeeded by a severe frost, which killed to the ground nearly all the cane standing in the parish; few of our planters having taken the precaution of windrowing. Since the frost on Sunday night, many have windrowed with a view of preserving the cane from the influence of the sun. This it will do to a certain extent. On Monday morning, the 1st instant, at daylight the thermometer stood at $37\frac{1}{2}°$. This was the severest cold we have had to injure the cane since 1842. In that year, in a central part of this parish, on the 19th November, at daylight, the thermometer stood at 26°, and the cane was killed to the ground. In 1832, on the 22d October, we had a frost which killed the cane throughout this parish before a hogshead of sugar was made. The crop was short, and the sugar was of inferior quality. The crop of this year will be cut short in our parish *one-fourth*, and in all other parts of the State in the same proportion."

From other information we also learn that a loss was anticipated from the severe effects of frost. The New Orleans Bee estimates the sugar crop of Louisiana at 156,000 hogsheads, as it falls short in fifteen parishes about 36,000 hogsheads. The actual returns for 1844 appear to have been about 191,000 hogsheads. Others estimate the decrease at about 20,000 hogsheads. The estimated decrease in the crop of the whole State by one informant is about "fifteen per cent." More have gone into the cultivation, which balances the loss; which otherwise would have been, perhaps, from 25 to 50 per cent. There will, however, be a larger quantity of molasses than before.

The crop of sugar in Florida promised fair, and the prospects of success were good. Quite a number have engaged in the business, so that the

whole crop of Florida is probably fifty per cent. more than before. The following statement presents the views of a public journal in that section of our country, respecting the appearance of the crop and its future promise as a staple for that new State: "We are informed that the sugar crop of this year promises fair, and that those of our planters who have engaged in the cultivation of its products feel well satisfied with their success. The short space of time which has elapsed since the termination of hostilities with the Indians has not permitted them fully to recover the position they occupied before the war, and consequently the crop of this year will be comparatively limited. Several of our planters commenced grinding the cane during the last week, and the smoke of the sugar mill curls up from many a lonely settlement between this place and Matanzas. We understand that large preparations have been made to increase the cultivation of their products during the next year, and we feel confident that the time is not far distant when the sugar crop of East and South Florida will form an important item in the agricultural resources of our State."—*Jacksonville News.*

The following is said to be a correct statement of the sugar crops in Louisiana for 1843 and '44:

Comparative statement of sugar produced in Louisiana in 1843 *and* '44.

	1843. Hogheads.	1844. Hogsheads.
St. Mary	15,311	18,795
Ascension	10,633	19,225
Iberville	9,644	16,463
St. James	9,350	21,519
Lafourche Interior	6,732	14,205
Plaquemines	6,641	14,761
Terrebonne	6,366	12,661
Assumption	6,256	11,990
St. Charles	5,882	12,532
St. John the Baptist	5,743	13,575
Jefferson	5,453	11,218
West Baton Rouge	3,087	4,247
St. Martin	2,621	4,419
East Baton Rouge	2,334	4,474
St. Bernard	2,026	6,941
Lafayette	908	372

Point Coupee	246	888
Vermillion	-	862
Divers small parcels	-	1,000
	100,346	191,324
		100,346
Increase		90,978

The following somewhat amusing account of the progress of improvement in sugar-making is from the Planters' Banner of September 20th:

" *The sugar business in Attakapas.*—Averse as most of our planters are to innovations and improvements, it is curious to notice the progress they have made within the last thirty or forty years. Indigo was the first article raised in St. Mary for export. It was not then thought that cotton-raising could be engaged in with profit; and if any one spoke of our soil as suitable for sugar, he would be looked upon as crazy. Cotton *was* engaged in with profit, and it was *thought* by some that sugar might be produced. The experiment of raising the latter crop was tried near New Orleans, and it was said the result proved satisfactory. Still, few had the courage to try it. The business gradually extended along the coast. At last, some seed-cane was brought to Attakapas, and some enterprising person invested a small sum in the purchase of *salt kettles* in New Orleans. These were placed between gum logs beneath an open shed; a mill was made of live-oak, and the experiment was tried. A few barrels of very inferior sugar were made and shipped to the city on a *keel boat.* The crop yielded a good profit, and those who had ridiculed the idea of making sugar in Attakapas followed the example. The salt kettles were set in brick and mortar, and sugar-houses of pine, with brick chimneys, were built. Much difficulty was experienced in boiling. Some made sugar of a very *dark* color, and others failed altogether the first season. Gradually, however, the quality of the sugar improved, but the chimneys were constantly cracking and falling down! The plan of building with double flues was discovered, and the difficulty was thus overcome. The planters, who had now become manufacturers, were quite elated; they built better houses, procured larger kettles, coated their live-oak cylinders with metal, purchased negroes, &c., and began to put up their sugar in hogsheads. Demand increased for carpenters, coopers, brick-makers, blacksmiths, &c. The sugar was of fair quality, and brought a good price. It was said that steam was used on the Mississippi, but of course the idea was ridiculed. But mules and horses were gradually superseded by steam-engines on the coast. Improved metal mills were now adopted, and some one in Attakapas *did* put up an engine! The quality of the sugar was now *fine.* Larger kettles were procured, but the sugar was not of so good a quality. The *small* kettles made the best article. *Clarifiers* were now used on the coast, and many experiments were tried. Some one in Attakapas *did* get clarifiers, but not more than three or four have, as yet, followed the example. Thus far, down to the present time. It is now said that *precipitators* are used on the coast; and this season, for the first time, they are to be tried in Attakapas. *Now* the big kettles will boil as well as the *little* ones! *We shall see.* In the year 1825 the crop of sugar and molasses made in St. Mary was taken to New Orleans by Captain Elam Patterson, in a keel boat of forty tons! Now, the crop of sugar is 20,000 hogsheads! So much for some of our wiseacres who are so inveterately opposed to improvements!"

Again: The statement of Mr. Chapommier of the crop of 1844, found in the appendix, presents some interesting particulars. We have added, also, the remarks of the New Orleans Price Current of September 1, 1845, respecting the sugar crop of the season past.

A discovery is mentioned in a New Orleans paper, by which molasses and sugar may be rendered perfectly transparent. We have seen no further notice of the same. " We are informed that a gentleman of this State has discovered a chemical process, which will enable him to make molasses and sugar perfectly transparent. It is his intention to take out a patent-right

forthwith. He has already made arrangements with several planters to operate on the forthcoming crop; and he is to receive, the first season, the difference in price between the old process and the new one. We further learn, it is estimated that the coming crop of sugar will fall short 20,000 hogsheads, in consequence of the damage the cane has sustained."—*New Orleans Native American.*

In the last report, mention was made of M. Rillieux's process for the manufacture of sugar. Since then, a letter was forwarded to the late Commissioner of Patents, in March last, containing a statement by Mr. Packwood, which relates to this method of manufacture, which it is presumed may be interesting to some; and it has therefore been placed in the appendix No. 12, above mentioned. Another letter, likewise received by the late Commissioner from Joseph Balestier, esq., U. S. consul at Singapore, giving an account of the mode of manufacturing sugar there, is added to the same class of papers.

The following analysis of the sugar, by Mr. Herapath, may be useful in showing the kinds of soil and culture best adapted to the same. It is probably made with reference to the West India cane.

"*Analysis of sugar cane, by Mr. Herapath.*—1,000 grains of sugar cane being burned, gave $7\frac{1}{2}$ grains of ash; and these being examined, were found to contain—

Silica - - - - - - -	1.780
Phosphate of lime - - - - - -	3.402
Red oxide of iron and clay - - - - -	0.176
Carbonate of potash - - - - - -	1.467
Sulph. of potash - - - - - -	0.150
Carbonate of magnesia - - - - -	0.430
Sulph. of lime - - - - - -	0.058
Grains - -	7.463

Judge Rost, in his address before the mechanical and agricultural association of Louisiana, gives an interesting description of the first attempt to make sugar in Louisiana; which shows from how small beginnings the great crop now raised of this article has proceeded. He says: "How is it with the sugar-cane in Louisiana? It was introduced here at an early day from the West Indies, and cultivated to a small extent at Terre aux Boeufs, and in the neighborhood of New Orleans. Nobody at first imagined that sugar could be made of it. The juice was boiled into sirup, which sold at extravagant prices. In 1796 Mr. Bore, residing a few miles above New Orleans—a man reputed for his daring and his energy—formed the desperate resolve of making sugar. He increased his cultivation, put up the necessary buildings and machinery, and procured a sugar maker from the West Indies. The day appointed for the experiment was come, and the operation was under way. The inhabitants of New Orleans and the coast had assembled there in great numbers. But they remained outside of the building, at a respectable distance from the sugar maker, who they looked upon as a sort of magician. The first *strike* came, and he said nothing; this they thought fatal, but still they remained fixed to the spot. The second strike was out; the sugar maker carefully stirred the first, and then, advancing towards the assembled crowd, told them with all the gravity of his craft: 'Gentlemen, it grains!' 'It grains,' was repeated by all. They

rushed in to see the wonder; and, when convinced of the facts, scattered in all directions, greeting everybody they met, with 'It grains.' And from the Balize to the Dubuque, from the Wabash to the Yellowstone, the great, the all-absorbing news of the colony was, that the juice of the cane had grained in Lower Louisiana. It did grain; it has continued to grain; it has grained the last season at the rate of 215,000,000 of pounds; and, if no untoward action of government prevents it, in ten years it will grain to the extent of more than double that quantity."

Maple sugar forms an important part of the sugar crop of the United States. It is true that it does not bear comparison with cane sugar; but in many States it furnishes a valuable substitute, which is as well relished, and saves the hard-toiling farmer from the purchase of the article foreign to him. The information we have been enabled to obtain respecting this crop, leads us to conclude that it is considerably above the usual crop. Vermont produces more maple sugar than any of the New England States. The Montpelier Watchman of May last estimated the sugar crop of that State for 1845 at $1,000,000 in value. The annual amount produced in the town of Leverett is 13,925 pounds; which, at 9 cents per pound, would be $125,325.

In the Boston Cultivator we find it stated that a sample of maple sugar, from Joseph M. Stevens, Caledonia, Vermont, made by him, had been received at the office of that journal, which the editor pronounces to be the purest and whitest he had ever seen. "The process is said to be simple and easy. Mr. L. manufactured, on his premises, last spring, 4,500 pounds."

In a letter addressed to the New York Tribune, dated Windsor county, Vermont, April, 1845, the writer says: "We are just through our annual sugar season, and all feel satisfied. The crop is large, and many have made 1, 2, and 3 tons."

From another source we learn that in Windham county there has been a large increase, owing to the improvements that have been made in the manufacture. The single town of Wilmington is said to have yielded, the last spring, 150,000 pounds. It is believed that the estimate for 1844 was perhaps not quite large enough, and that the crop of 1845 was not less than 10,000,000 pounds.

There was also an increased crop in New Hampshire and Maine, owing to the increased attention paid to its production. In some parts of Massachusetts, too, there are large quantities of maple sugar manufactured. The amount produced in the town of Leverett, as ascertained by the assessors, was 17,473 pounds. In New York there was a considerable increase over the crop of 1844, varying from 10, 15, to 20 per cent. Similar estimates are presented from other States and sections of the country where this product is raised. In a few only do we notice any falling off. This was the case in Kentucky and Ohio, which furnish a considerable quantity. In Indiana and Michigan the crop improved.

In order to obviate the objection which exists in the consumption of wood that must necessarily take place where the maple sirup is evaporated two or three times, the following method has been suggested, by which an individual of moderate means has been known to make over a hundred pounds of the purest white sugar in one season: "The tubs for collecting sap, as well as those in which it is kept ready for boiling, must be perfectly clean, and scalded with lime-water before using. If it should be warm weather during the sugar season, put into the reservoir a piece of lime about the

size of a hen's egg for a hogshead of sap. Pour it out through a strainer, and observe the strictest cleanliness through every part of the operation. When it is boiled down enough, let the sirup stand over night to settle. It is then to be strained off the sediment through a flannel. Dissolve the sediment again in water and boil it; boil down the strained sirup till it is thick enough for crystalizing. Let it then be put into tubs, and grow cold and harden; bore holes in the bottom and drain off the molasses, and when all the molasses is thus drained off, cotton or linen cloths of some thickness are laid on the top of the sugar and constantly kept wet. The sugar thus receives a regular and constant supply of water, and gradually soaks down through the crystalized, dissolving the molasses and other impurities, which drain off and leave the sugar perfectly pure and white."

The labor of this process is said to be light, though some weeks must be allowed for it. The specimens of maple sugar which have recently been exhibited in some of the agricultural fairs in Vermont and New York are said to have been uncommonly fine, and as white as the purest loaf sugar. We believe that the manufacture of this article may be carried on profitably to a much greater extent than it has hitherto been; and in most instances the farmer has leisure to attend to it, as it occurs at a period of the year when he cannot attend to other crops. In appendix No. 13 will be found a valuable paper, from an able western agricultural periodical, on maple sugar and the extension of its production in our country.

The whole sugar crop of the United States, including both cane and maple sugar, amounted, according to the best estimate at which we can arrive, to 216,026,000 pounds.

Cornstalk sugar.—The attempts are still continued to produce sugar from the cornstalk. The same difficulty respecting granulation, &c., still remains as before. But we can scarcely doubt this will yet be overcome. Mr. John Beal, of New Harmony, Ia., whose letters were given in the last report, still continues sanguine in regard to this matter. That molasses of a good quality for use can be produced, seems to be very evident.

The following notices appear in different public journals:

"*Molasses.*—This useful domestic article is now made out of cornstalks, and a very superior quality has been produced by Mr. Samuel Moreland, of Carthage, Tennessee. Mr. Moreland says the juice yields about one-fourth, as well as he can guess from the experiment he has made. The process appears to be simple enough. Press the juice out of the stalk about the time it arrives at maturity; boil it as you would the water from a sugar tree, until it becomes as thick as you want it; then your molasses is ready for use."

Again: "*Cornstalk sugar.*—The Albany Cultivator gives a little additional information on this subject. In an experiment mentioned, one pint of flour was mixed with two gallons of skim milk, and one pint of this mixture was added to thirty gallons of juice. This prevented any decomposition of sugar during the process of evaporation, and is supposed to make success surer. As the juice comes from the mill, it should run into a receiver which will hold just enough to fill one of the kettles or pans; while in this receiver the mixture of flour and milk, and also the necessary quantity of lime, must be added and well stired in. It is then poured at once into the boiler and heat applied; a very firm thick scum is by this means separated, and the juice becomes clear. It is then run into one of the evaporating pans, and the boiling kept up briskly. As the boiling proceeds, it is re-

commended to throw occasionally a shovelful of red-hot coals into the pan, having first blown the ashes off. As you put in more juice, add more coals; and as the pan becomes filled with coal, take out that which was first put in. This is done in the first stage of the boiling process. The pan for finishing should be shallow, and have but a depth of two or three inches of sirup in at one time."

Again:

"*Cornstalk sugar and molasses.*—We have received from John Beal, of New Harmony, Indiana, samples of cornstalk sugar and molasses manufactured by him the past season. The sugar is equal in quality to any of that kind we have seen, with the exception of a single sample, which we understood to have been made by Mr. Webb, of Delaware. The molasses is clear and thick, but retains a little of the peculiar pungency in taste which seems to attend more or less that which is made from cornstalks. But we can hardly doubt that improvement will be made in the process of manufacture, by which these articles will be produced of a better quality. It should be considered that the business is yet new, and, of course, partakes of the imperfection attending all untried enterprises. The communication of Mr. Beal having been mislaid until too late for this number, will appear in our next."—*Cultivator, December.*

In appendix No. 13 we give Mr. Beal's letter above mentioned, from the Cultivator of January, 1846; also, a letter from Mr. Beal to this office, enclosing a sample of his sugar, which had very much the taste of some of the coarser sale sugars. Mr. Beal states that he has been more successful the past season than before. On a measured acre he obtained about 700 pounds of crystalizable sirup. It was also of a better quality than before. He still finds some difficulty in the drainage, and thinks if it could be kept in a temperature of 70 to 80 degrees the process would be accelerated. His yield, he says, was equal to 57 gallons per acre; and, estimating his sugar at five cents a pound—a low estimate, as cane sugar there usually ranges from eight to twelve cents a pound—he gives the net value of the sirup on the acre at $14 90; which, compared with merely raising corn, leaves a balance in favor of sugar of $3 40. He thinks, also, that on a large scale it would be still more profitable. He further says that the continued culture of corn for the purpose of making sugar is now a settled point with him; and that in general it is as profitable as any thing else there, though in some years there may be exceptions in favor of particular articles. His letter contains his calculations in detail.

In Prescott's Conquest of Mexico, the interesting fact is stated that the Mexicans were accustomed to make sugar from cornstalks. In communicating a notice to this effect to the Cultivator, a writer from Staten Island, signing himself Richmond, and now known to the public as Dr. Samuel Ackerly, expresses his sanguine belief that before long we shall see and consume cornstalk sugar in abundance. The extract to which we allude is as follows: "The great staple of the country, as indeed of the American continent, was *maize* or *Indian corn*, which grew freely along the valleys and up the steep sides of the Cordilleras, to the high level of the table land. The Aztecs were as curious in its preparation, and as instructed in its manifold uses, as the most expert New England housewife. *Its gigantic stalks in these equinoctial regions afford a saccharine matter not found, to the same extent, in northern latitudes, and supplied the natives with sugar little inferior to that of the cane itself, which was not introduced among them*

till after the conquest in 1519." Dr. Ackerly adds: "If a semi-civilized nation on the continent of America, more than 300 years ago, made sugar from the stalks of Indian corn, why may not the more civilized races of the present day, with the aid of art and science, do the same? There is no doubt that it may be done—it has been done. The experiments that have been made show that it can be done; but in which of the States it can be most advantageously adopted, remains to be decided by other experiments. I remember when maple sugar could only be obtained of the blackest and coarsest kind, such as was strained through the dirty blankets of the aborigines, and sold in small cakes or birch baskets as a rarity." "Now," he states, "even rock candy has been exhibited at the State fair, which had never before been made from the sap of the maple tree. Maple sugar was always made in small quantity, but of late years a large amount is manufactured and refined equal to the best imported sugar. So will cornstalk sugar be gradually improved and introduced."

The account we have given of the introduction of the cane-sugar culture in Louisiana, is certainly encouraging to those who are experimenting with the cornstalk.

The cultivation of the sugar-beet in France, and other parts of the continent, is well known. In the former kingdom, large quantities are manufactured. Some attention, and increasingly so, is paid to the same culture in Great Britain. On this, a public journal thus says: "The amount of beet-root sugar manufactured in Great Britain and Ireland in 1844 was 5,597½ cwt.—an increase of 1,753¾ cwt. compared with 1843. Of this, 3,420 cwt. were manufactured at Stratford, in Essex; the remainder at Liverpool, and Portaferry, Downshire."

The *Journal du Commerce*, of Antwerp, mentions the discovery of a *new* kind of beet, which is much superior in all respects to the ordinary sugar-beet for the extraction of sugar. This may be the same as a species which is partially described by Dr. Medicus in the *Central Blatt*, of Bavaria, which is said to be fourteen days earlier, and on this account possesses decided advantages over the usual species; and which he recommends for cultivation by the producers of this article. According to the French papers, the state of the French sugar manufactory in 1844–'45 (of beets) was as follows: Manufactories in work, 294, or 31 less than last year; manufactories not in work 21, or 29 less than last year; quantity of sugar was 32,373,449 kilogrammes, or an increase of 5,598,054 kilogrammes on last year.

OTHER PRODUCTS, AND NEW ARTICLES FOR CULTIVATION.

The *root* crops stand next in importance to those enumerated in the table. As they did not enter into the returns of the census of 1840, we have no basis on which to found any general calculations; but they occupy a valuable place in the agricultural and horticultural pursuits of our fellow citizens.

We may form some idea respecting the crop of *turnips* from the fact that, according to the late census of the State of New York, there were raised in that State, in 1844, 1,350,332 bushels of this product on 15,322 acres of land devoted to such a purpose. In regard to most of this crop, it is presumed that there was no special attempt to raise large crops. The culture of turnips is prosecuted in Great Britain with great care; and very large

crops are often secured. Some valuable papers on this subject are to be found in the English periodicals, from which we feel strongly tempted to quote, but that they are too long, and depending in their results on comparison with extensive tables, which it may not be advisable to transcribe. It is a favorite and successful crop in that country, and great attention is paid to its production, as well as reliance on it for feeding stock.

We have met with some statements of the successful cultivation of *carrots* in our country, one or two of which we here subjoin.

"For The Farmers' Monthly Visiter.

"More than 1,218 bushels of carrots to the acre!

"Mr. Editor: When you were at our establishment a few days ago to look at the swine that obtained two premiums at the late fair in Boscawen, you mentioned several instances of large crops of carrots raised the present season, and you spoke of ours as looking well. This induces me to send you this statement of our success. We had just one-fourth of an acre sowed on a piece of ground, a part of which, two years ago last spring, was covered with laurel and white birches. The soil is a light loam on a sandy substratum. It was ploughed deep, and highly manured, and dressed over with leached ashes. The seeds were sown in drills one foot apart, with a seed sower constructed by one of our patients; and when the weeds were hoed out it was designed to leave the carrots standing about four inches apart in the drills. The carrots gathered from this quarter of an acre measured 304½ bushels, besides what had been gathered previously for cooking. Most of the carrots were long, smooth, and large. The heaviest weighed 3¼ pounds. This is at the rate of 1,218½ bushels to the acre. What crop is there more profitable? The 6 or 8 patients who assisted the farmer in digging them were highly delighted with such a return for their summer's labor.

"Very respecfully,

"GEORGE CHANDLER.

"N. H. Asylum for the Insane,
"*Concord, November* 7, 1845."

Again: "Mr. C. F. Crosman, of Brighton, has raised, the past season, 410 bushels of carrots on one fourth of an acre. This is at the rate of 1,640 bushels per acre. Mr. C. has also grown something like 1,000 bushels of beets on one acre of land. He is extensively engaged in the seed-growing business, producing several thousand dollars' worth annually."—*Genesee Farmer, January*, 1846.

The white, or Belgian carrot, as raised in England, sometimes produces 30 tons to an acre. In the Journal of the Royal Agricultural Society, volume 5, we find a paper by sir Charles Burrall, recommending highly the culture of this root, as a means of economizing hay. He says that, in the spring of 1843, five acres were sown—4½ with white, and one-half acre with red Altringham carrots—in order to compare them. The sowing of the Altringham did not prove successful, nor one-half acre of the white; consequently, he had but 4 acres, which produced 1,200 bushels to the acre; and with these, adding equal quantities of Swedes turnips, and some hay and oil cake, he fed 24 fatting beasts to April; besides which, he further applied his carrots to feeding 24 cows and 2 bulls with great economy of

hay. He proves this as follows: "In 1842—238 acres, and grass produced 200 loads of hay; and when hay-making commenced in 1843, I had about 50 loads of old hay only in reserve. In 1843, 260 acres of seeds and grass produced 505 loads of hay, besides 21 acres of clover, producing 19 loads; and I had about 400 loads of hay in reserve, when hay-making commenced in 1844; showing a beneficial reserve of hay, chiefly to be attributed to the united effects of a very good crop of hay in 1843, and the reduction of its consumption by the use of white cattle-carrots, &c." He says, also, that he has a very promising crop of flax after the carrots, without any dressing.

Among other crops which are included in the New York State census, are *peas* and *beans*—of the former, the returns give for the State 1,761,503 bushels, and of the latter 162,187 bushels. In the Southern Planter, for May, 1845, we find mention of a variety of pea, called the Rocky mountain pea, which perhaps may be profitably introduced into culture among us. "We have also received from Mr. Haxall a paper of peas, called the Rocky mountain pea, concerning which he has furnished the following statement: In calling public attention to these peas, I am well aware how often our citizens have found themselves deceived by ardent descriptions on the one hand, or dreamy promises of profit on the other. These peas, however, will answer any reasonable expectation. I planted five quarts of them about the 20th of May, in a piece of rough new ground, of sandy soil and only middling in quality. The product in peas and in rich good hay exceeded any thing I have ever seen. Whether we wish to save them as hay for cows, horses, or mules, or to turn stock upon them as upon cow peas, or to improve the land by their decay, they are, in my opinion, far better than any common pea. To instance only one thing: I planted them alongside the red cow pea; a dry spell in August arrested the further product of the common pea; the vines were leafless and dead; while the Rocky mountain pea was green and flourishing, and bearing peas, in an increased proportion, until the severe white frost the last day in October. They grow more like a cotton plant; do not entwine about the corn, and consequently may be saved with ease for hay. They should be planted by the 1st of May, in good land, and not more than four in a hill; plant them as you would the common pea. They come up quickly, grow rapidly, and commence bearing as soon as the common kind.

"L. PIERCE."

In the Southern Cultivator, for November, 1845, a statement is made respecting the Chickasaw pea, which is here subjoined. "A correspondent of the South Carolinian, writing from Greenville, speaks in very high terms of the Chickasaw pea as a fertilizer. If this pea, after extensive trial, continues to answer the expectations that have been formed of it, we need not, in the southern States, complain that clover will not succeed with us. We will have in this pea what will answer our purposes just as well. We shall be glad to hear more of it from those who have tried it; and especially if it be not the same as what is known as the *tory pea* in Alabama and some parts of Georgia. The account by the South Carolinian's correspondent is as follows: 'There is perhaps no section of country in the upper districts which has improved more in agricultural condition than the Old Pendleton neighborhood—the result, we are told, of an agricultural society, composed of intelligent and practical farmers. We were struck with the

manifest improvement in the breeds of cattle and hogs. The Berkshire cross has here told well; for the very simple reason, we presume, that stock is attended to. We have never seen a finer stock of hogs in travelling through any country. More attention seems to be paid to the pea culture here than any section we have been in. We are told that it is the opinion of many good farmers hereabouts, that land can be improved to a high degree by the pea culture. We have no doubt of the fact, if properly applied. There is a pea—the Chickasaw pea—which bears most abundantly, and, once planted, is almost inextirpable. We have seen it put into corn ground after the corn was taken off; pastured by the cattle and hogs all winter; in the spring put in oats, and after the oats were taken off the pea came up in great abundance. Now suppose these were to be let alone; and, in lieu of the absurd system of pasturing stubble, the vine and stubble should be turned under in the fall; would not the land be vastly improved? We have no doubt, if the pea were sown on our stubble lands, a peck to the acre, and the crop turned in while in the bloom, that the effect produced would be equal to the best clover leas, so much esteemed in Virginia and the north. It is an admitted fact, that leguminous plants exhaust a soil in a very slight degree. The pea vine contains about 53 per cent. of potash—a most important ingredient in all soils for the production of grain or cotton. If this should be returned to the soil, in addition to the carbon and nitrogen contained in the vine, it seems to me that there would be a manifest improvement. It has been discovered by analysis that cotton-wool contains, potassa 31.09 per cent.; lime, 17.05; magnesia, 3.26; phosphoric acid, 12.30; sulphuric acid, 1.16; potassa, 19.40. While corn contains potassa, 20.87; phosphoric acid, 18.80; lime, 9.72; magnesia, 5.76 per cent. The following analysis of straws may not be uninteresting:

	Wheat straw.	Barley straw.	Oat straw.
Potash	$\frac{1}{2}$	$3\frac{1}{2}$	15
Soda	$\frac{3}{4}$	1	15
Lime	7	$10\frac{1}{2}$	$2\frac{3}{4}$
Magnesia	1	$1\frac{1}{2}$	$\frac{1}{2}$
Alumina	$2\frac{3}{4}$	3	$2\frac{3}{4}$
Oxide of iron	$2\frac{3}{4}$	$\frac{1}{2}$	$2\frac{3}{4}$
Silicia, or flint	81	$73\frac{1}{2}$	80
Sulphuric acid	1	2	$1\frac{1}{2}$
Phosphoric acid	5	3	$\frac{1}{4}$
Chlorine	1	$1\frac{1}{2}$	$\frac{1}{4}$
	100	100	100

'From the foregoing data we learn that potash is a most important ingredient in cotton and corn, and that the pea vine and cotton seed would be most invaluable manures. How easy would it be to avail ourselves of both. If a planter should sow twenty bushels per acre of cotton seed upon a luxuriant vine crop, and put it in wheat, is it not reasonable to suppose that the advantages derived would be as great as from a clover lea or gypsum? We are sure the elements are nearly the same, and we have no doubt of its effect. It is an admitted fact, we believe, that oats exhaust land more than any other grain crop. The mystery is solved, we think, by the analysis, for thereby oats are found to contain 15 per cent. of potassa, while barley straw contains only three and a half, and wheat one-half per cent. No

doubt the rapid growth of oats and close pasturing aids much in the exhaustion of the soil; and we derive an important lesson from the analysis —the want of potassa in the soil, which may be supplied by the pea crop and keeping off one's stock. Grass does not exhaust a soil, for the very simple reason that it takes up no potash. Grass contains—carbon, 45 per cent.; hydrogen, 5; oxygen, 38; nitrogen, $1\frac{1}{2}$; and ashes, 9 per cent. We look forward to a day when the pea crop will be found a most important auxiliary in the resuscitation of the worn out lands of the south. Clover cannot be grown here; the climate is altogether too hot to expect a luxuriant growth to answer for manure. We see no resource left us but the pea culture.'"

Mr. Boussingault, in his Rural Economy, after giving the various equivalents of products as compared with wheat, says: "Judging from the equivalents, leguminous vegetables must be possessed of a much higher nutritive value than wheat; and it is known, indeed, that peas and beans form in some sort substitutes for animal food. The difference indicated, however, is so great that it may surprise those who have never thought of the subject."

The Genesee Farmer of July last says: "The soil best adapted to peas is a loam, a little inclining to clay. Early sowing is important, even if before snow and frosts are past. Sow at the rate of two to three bushels per acre, according to size; and even more, if buggy. They succeed best when ploughed in with a light furrow from four to five inches in depth, and harrowed down smooth for convenience of gathering. On good soil, the general yield is from 30 to 40 bushels per acre, and weight about 50 pounds."

Onions, also, under some circumstances, are a profitable crop. The average yield of this crop in Essex county, Massachusetts, is stated to be 300 bushels to the acre, and sometimes as high as 500 or 600 bushels. The *ordinary* expense is estimated at double that for Indian corn. For ten years past it is said from 30,000 to 40,000 bushels a year have been raised in Danvers alone, at a value of 50 cents per bushel, or $150 per acre. In appendix No. 14 will be found an account of a method of raising onions and carrots together, by which 1,209 bushels of carrots and 630 bushels of onions were raised to the acre.

Our country, within a few years past, has made great advances in the production of choice *fruit*. Many in all sections of the United States have turned their attention to this object, and the result has been great improvement in orchards, and the introduction of better methods of cultivation. Treatises of real practical value have been published to aid in this design, and much horticultural knowledge has been diffused among the people. There seems to be a prospect that this subject will occupy yet more attention of our agriculturists; and to some it has been, and promises further to be, a very considerable source of revenue. Our apples already command a high price in England, where the palm is invariably awarded to them when brought into comparison with those of home production there. Our principal cities and towns exhibit (in their season) at times a great profusion of various fruits in the markets.

The past year proved especially favorable in some sections to *peaches*. The vast quantities of this fruit produced in Delaware by Major Reybold & Sons is well known to almost all in the city of Philadelphia, which is their principal market. A writer in one of the papers, giving an account of his visit to these orchards, says: "From the books of Major Reybold

and his son were ascertained the following remarkable facts: Quantity of peaches sent to market (to the 29th of August inclusive) by Major Reybold, from his Maryland and Delaware orchards, 31,145 baskets; John Reybold, 13,300; Philip Reybold, jr., 6,000; William Reybold, 5,699; Barney Reybold, 7,200. Total number of baskets, 63,344. Number of baskets employed for transit, 40,000 to 50,000. Number of acres of orcharding, 1,090. Number of trees in orchards, 117,720." Steamboats were constantly arriving and departing loaded with the produce of these orchards, which were sent to New York and Boston, as well as to Philadelphia and near markets. It is probable that before the close of the season as many as 80,000 baskets, if not more, were thus disposed of from these orchards.

The Tribune estimates the whole number of baskets of peaches sold in New York during the last peach season, of forty days, at 12,000 per day, or 480,000 baskets, at a cost of three-fourths of a million of dollars; and says, that there are more peaches offered for sale in New York annually than are raised in France.

Nor is Cincinnati less favored with regard to *strawberries*, a delicious fruit of the earlier season.

A Cincinnati paper states: "There are about 25 days of full sale of strawberries in this market. At 4,000 quarts per day, this gives 100,000 quarts of strawberries sold in this market in one season. They average 8 cents per quart, which makes $8,000 paid in a little more than three weeks for strawberries." Some very fine varieties of this fruit are produced by our horticulturists. In the Cleveland Herald we find the following:

"*Magnificent strawberries.*—Friend McIntosh has presented us with two baskets of the finest strawberries we have tasted this season. One contained the Ross Phœnix variety, a seedling, first grown by Mr. Alexander Ross, of Hudson, New York, and fruited by that gentleman for the first time in 1840. Mr. McIntosh introduced it here, at a cost of $1 50 per dozen plants, and is much pleased with the variety. It is a strong grower, prolific bearer, large berry, of excellent flavor, and bids fair to equal Hovey's celebrated seedling. Several of the berries in the basket before us measure 4 and 5 inches in diameter, and we counted 18 berries in different stages of growth on a single truce or stem. The other basket is filled with tempting grove and scarlets, an old and well known variety, and one of the most abundant and profitable bearers. Plants of the above and other valuable varieties can be obtained of Messrs. McIntosh & Co. The best time for forming new beds is early in August."

Another fine seedling is mentioned by the editor of the Cultivator, as observed at Palmyra, New York, in the garden of Col. J. S. Stoddard. He says: "Some years ago he raised about 2,000 new seedlings from the Alpine variety, one of which (a red variety) he selected, and has since increased. The ground occupied by this seedling is about 60 feet square, the plants standing in hills 14 inches apart. These strawberries bear their fruit above the leaves. In this case the masses of red berries presented so brilliant a glow as to be conspicuous several rods distant. He measured some of the fruit of this variety, which was one inch and a fifth long and more than three-fourths of an inch thick. Col. S. thought he should pick from this 60 feet square 35 bushels. He had taken from it and another smaller bed 2 bushels daily. They were sold for $4 per bushel."

The Cleveland Horticultural Magazine also contains some excellent remarks on the cultivation of another fruit, the *gooseberry*, which are here

extracted, thinking they might be useful to some: "Permit us now to offer our opinion regarding their culture. First select a soil, neither stiff clay nor loose sand, but of good, rich, deep mould, in a position where the mid-day sun will never reach. Plant your bushes 3 feet apart each way; train them into heads at least 2 feet from the ground; let the head be formed nearly round and open. After the head is once formed, attend to the bush from the time the blossom shows itself until the fruit is ripe, and whenever a branch is pushing forward to make wood, nip the end with the finger, thus throwing all the juices into the formation of the fruit, besides keeping the bush more open to the air; with the hoe dig well among their roots, being careful not to break them, but yet to keep the earth loose and moist. As often as once a week, from the time the fruit sets until ripe, bestow a watering of liquid manure upon the soil, and use the hoe directly after it. In pruning, let it be borne in mind that the gooseberry produces fruit not only on the wood of the preceding summer's growth, but also on spurs from old wood. The wood of the last past year, however, producing the larger berry, if possible to preserve a rightly formed head, it should be done. No bearing wood branches should be nearer than 6 inches of each other, and the shoots should never be more than 12 buds in length. Where old bushes have long remained, if not convenient to transplant to another position, (and for this year the season is now too far advanced,) take away the earth from about the roots, and shorten in all the larger ones by cutting to at least 1 foot in length each. This will cause them to form new spongioles in great numbers; and if the dressing of liquid manure is given as directed, they will afford a vast increase of nourishment to the plant. Should any appearance of mildew become visible, sprinkle the bushes with weak lime-water, and scatter lime and sulphur underneath upon the ground. If your bushes are now placed where they are directly exposed to the heat of mid-day suns, erect some temporary shade, or plant running beans and train them up as shades. The number of varieties is now increased to several hundreds; yet in 1743 there were but 6 or 7 sorts admitted as valuable."

Mention was made, in a former report, of *cranberries*. In the New York Farmers' Club some remarks were offered on this subject, in their discussion, which we here subjoin:

"*General Chandler*. I present to the club cranberry plants—some with their great crop of fruit on—at the request of Mr. Sullivan Bates, of Bellingham, Massachusetts. A few years ago he first exhibited this fruit, produced by his new method—transplanting from the low grounds which it affects, to high ground. His success has been complete. He has gathered from one acre about 400 bushels of cranberries in a season! He plants them in drills 20 inches apart, in hills 7 inches apart; and the quality of the fruit is improved by this new culture. The soil must be such an one as does not bake.

"*Chairman*. I took from swamps on General Johnson's place some cranberry plants, and planted them on ground 80 or 100 feet above the swamp; they thrived, and their fruit was so close together that one could hardly put a finger in without touching the cranberries. It is a highly profitable crop. I am of opinion that $500 might be obtained for a full crop of one acre.

"*General Chandler*. Mr. Bates will furnish any number of plants to those who desire it.

"*Mr. Worth*. The cranberry of Russia is larger than that of England;

but both of them are scarcely half the size of these cranberries, and of much inferior flavor. Those exhibited here would suit the English and continental markets, and would be sold to any extent.

"*Chairman.* I planted mine in loamy soil; prepared the earth well about the plants; watered them well; and did not lose 10 out of the 150 plants.

"*General Chandler.* And those which I sat out last spring lived and flourished.

"*Mr. Meriam.* The cranberry grows abundantly on our northern soils that are marshy. All agree that such is the habit of the cranberry.

"*Mr. Wakeman.* My family have tried Mr. Bates's cranberries, and have found them excellent; and they are larger than other cranberries."

* * * * * * * *

For an article on the culture of cranberries, see appendix No. 15.

We may here allude to another species of fruit, respecting which an English paper observes, that in Father Ripa's account of China, translated by Mr. Piandi, (a work republished in this country lately,) the Chinese *quinces* are said to be much larger than the English ones, and of an exquisite quality, consisting almost entirely of juice, so that when dried in the sun nothing but rind remains.

The fine apple orchards of R. L. Pell, of Ulster county, New York, have been mentioned in many of the public journals. He obtained the gold medal from the American Institute for the best fruit farm in the State. He has furnished an account of his management in one of the agricultural papers, and we give it here as important and highly useful. His statement is addressed to the committee on fruit trees, viz:

"Gentlemen: Being desirous to compete for the premium to be awarded by the American Institute, at its sixteenth annual fair, for the best fruit farm in the State, I now abide its rules, and offer, at the request of Mr. T. B. W., its worthy and very useful secretary, my mode of managing. For some years I have been experimenting upon the apple tree, having an orchard of 20,000 Newton pippin apple trees. I have found it very unprofitable to wait for what is termed the bearing year, and consequently it has been my study to assist nature so as to enable the trees to bear every year. I have noticed that it bears more profusely than any other tree, and consequently requires the intermediate year to recover itself by extracting from the atmosphere and the earth the requisites to enable it to produce. If unassisted by art, the intervening year must necessarily be lost. If, however, it is supplied with the proper sustenance, it will bear every year. Three years ago in April, I scraped all the rough bark off a few of the apple trees in my orchard, and washed the trunks and limbs within reach with soft soap, trimmed out all the branches that crossed each other early in June, and painted the wounded part with white lead, to keep out the moisture; then split open the bark by running a sharp-pointed knife from the ground to the first set of limbs, in the latter part of the same month, which prevents the tree from becoming bark bound, and gives the inner wood an opportunity of expanding. In July I put one peck of oyster shell lime around each tree, and left it piled about the trunk until November, when I dug the lime in thoroughly. The following year I collected from those trees 1,700 barrels of fruit; some of which was sold in New York for $4, and the balance in London at $9 per barrel. Strange as it may appear, they are literally bending to the ground with the finest fruit I ever saw; a

specimen of which is before you. The other trees in my orchard, not treated as above, are barren, next year being their bearing year."

Alluding to Mr. Pell's orchard, and urging the cultivation of fruit on his readers, the editor of the Southern Cultivator says: "Mr. Pell, of Westchester, New York, has an apple orchard of 20,000 trees. He sells his apples in New York at $6 per barrel. The best, however, he sends to England, where they command $21 per barrel. The nobility and the wealthy people bought them last year at a guinea a dozen, or about 45 cents a piece. Last year he sold 9,000 barrels. This year he has already sold between 3,000 and 4,000 barrels. Scotch physicians prescribe American apples for dyspepsia. It is no unusual thing for an English lady to have on her table, at a party, fruit which costs from £400 to £500. A dinner was given by an English nobleman, some years ago, for which the fruit alone cost £6,000. Invariably, where English and American apples are exposed for sale together in the London fruit shops, the American are preferred at double the price of the English."

The cultivation of the *grape* is also a pursuit which, it is probable, will hereafter become extensively engaged in throughout our country. It is already successfully raised both for wine and for the table. A committee, appointed by the Cincinnati Horticultural Society, in 1844, to report on the subject, examined thirty-nine different specimens of wines produced in that neighborhood, and came to the following conclusion: (The full report is contained in appendix No. 16.) "The result of the examination is a conviction, on the part of the committee, that our soil and climate are well adapted to the production of a very fine, delicious wine; and that the Catawba grape is the species which yields the finest qualities. It will be seen that the greatest number and variety of the specimens examined were from the several vineyards of N. Longworth, esq., who has been longest engaged in the cultivation of the vines, and in the manufacture of wine. Mr. Mottier and Jacob Resor, esquires, who have lately acquired a good reputation in this department of horticulture, were next to Mr. Longworth, in the number and variety of the specimens furnished. These, with the single specimens of Dr. Flagg and the specimens of Dr. Smith, confirm the opinions of the committee, that the pure juice of the grape, when judiciously managed, will furnish the finest kind of wine, without any addition or mixture whatever; that no saccharine addition is necessary to give it sufficient body to keep any length of time in this climate. In confirmation of this opinion, we would state that two of our German friends who were present informed us that they had taken, on different occasions, specimens of the wine of this country to Germany, and submitted them to the judgment of various connoisseurs in that country, by whom they were highly approved; the principal or only objection being, that they were too strong to compare with the fine kinds of the lightest German wines. A taste for the wines of this region appears to be well established, since all that can be produced finds a ready market at good prices; and the committee are of opinion that the period is not distant when the wines of Ohio will enjoy a celebrity equal to those of the Rhine."

A letter to the Horticultural Society of that city, also found in the above mentioned appendix, from William Resor, gives an account of a vintage there, by which it appears that his net profit was $2,525 50. The letters of Messrs. Longworth, Locke, Weller, Brown, &c., also in the same appendix, deserve perusal.

The Louisville Times thus mentions the "*Vintage from the Catawba grape.* We understand that the vintage of this delightful wine now in process in our neighborhood, in Indiana, will yield this season nearly 3,000 gallons. The vineyards, although in their infancy, would have produced double that quantity but for the wet weather. As it is, this is the happy experiment on 16 or 17 acres of land. Several of our most experienced citizens have commenced graperies which are now in a highly prosperous condition. We learn that Mr. Longworth, of Cincinnati, has a vineyard of 90 acres, promising to yield near 20,000 gallons."

In other public journals we find the following: "We are gratified to learn that a wealthy German, from the banks of the Rhine, Mr. John Klinger, has purchased a plantation of 450 acres on the Alleghany river, near Kittaning, for the cultivation of the grape. He is sanguine in the belief that the foreign species of this delightful fruit will flourish there, and we have great confidence that all that is wanting is proper and intelligent culture."—*Philadelphia North American.*

Again: The Burlington (Iowa) Hawkeye says, "that a gentleman from the south has just purchased 60 acres of land near that town, on which he intends to raise grapes and fruit of the best quality on a large scale."

A variety of grape called the Winnie grape is described in the Boston Cultivator, which appears to be similar and yet somewhat different from the Isabella grape. The writer says: "Some weeks ago we examined a Winnie grape-vine on the farm of Wm. B. Kingsbury, of Roxbury, which was grafted on a wild vine in the edge of the bushes, and it ran over a high rock; and though grafted but a few years ago, it has produced a noble crop of fruit this season. We were treated with some noble bunches, and found the fruit excellent. Some have supposed that this fruit was identical with the Isabella, as it resembles it in appearance and quality, in hardness, vigor, and luxuriance of the vine, its great productiveness, its time of ripening, &c. But we find, by close examination, that the two are different. The Winnie has not quite so large bunches, but the berries are larger, and a less number of small ones. The berries of the Winnie are round, while those of the Isabella are almost invariably of an oval shape, and considerably elongated at the stem. We find that the Winnie and Isabella grapes, as well as other varieties, differ in different soils, locations, and climates, and we are not prepared to draw a comparison between the merits of the two. Some who have cultivated the two think that the Winnie is a little the earliest, less acid, and less of the foxy taste, and that it is, on the whole, the most valuable. We are inclined to favor this opinion, but we give it with the caution that it is best to try it in a small way for experiment. We have some vines of the Winnie which we find remarkably hardy and vigorous, but they have not yet fruited, and we have seen it only in a few cases."

Though it is a matter of doubt with many whether the cultivation of the grape for wine extensively in this country will be useful, yet all will unquestionably agree that, as *table fruit*, the more universal use of the grape among us is most desirable; nor do we see why the preparation of them for market as *raisins* may not yet be an important business in sections of our country, so that we shall not be obliged to depend upon Spain for this species of dried fruit, and may have a great abundance of delicious grapes for eating, which are both a luxury and highly salutary to the health of all classes.

Considerable was said in the last report relative to the culture of *mustard*

by Mr. Parmalee, of Ohio. We have added in the appendix (No. 17) some further accounts relating to this subject, and would also here refer to Mr. Parmalee's letters to Mr. Ellsworth, late Commissioner of Patents, and which are contained in appendix No. 1, of papers furnished by Mr. Ellsworth, as mentioned in his letter to this office. There seems to be some contradictory statements in the various articles, respecting which we offer no opinion, but present the different articles which contain the information as the fairest course for us to pursue in such a case. This office is under obligation both to Mr. Parmalee and to Messrs. Fell & Brothers, as well as the different editors of the agricultural journals, from which our extracts are quoted, for their readiness to afford such information as is in their power. There can be no doubt, we think, that the culture of mustard may be carried on profitably in our country. The editor of the New York Farmer speaks, in his No. for May last, of a visit to a mustard factory in New York city, and says he was there informed that most of the mustard in this country is imported from Holland and Germany. 10,000 lbs. were received from the Sandwich islands. The price varies from seven to nine cents per pound for the brown, and five to seven for the white. American seed is less plump, but retains its strength longer.

The Ohio Cultivator mentions 70 acres in that State devoted to this culture, yielding 700 bushels of seed. Messrs. Fell & Brothers, of Philadelphia, in their statement mention 760 bushels, or 39,109 pounds, for which they paid $2,669 78.

In one of the agricultural journals, we meet with the following recommendation of kiln-drying mustard: "Col. Clark, in a conversation during a meeting of the New York Farmers' Club, recommends kiln-drying mustard, in order to keep it. It may be put into a kiln or oven heated to about 140° of Fahrenheit's thermometer, and dried, and afterwards kept from light and air, and it will thus retain its pungency a long time, and be much better than it generally is. Mustard has been recommended as a profitable crop, but it is apt to shatter out and become a weed; or, in other words, 'a plant out of place.' This might be obviated by keeping a field devoted to it and sowed every year; or, if sown sufficiently thick, by being shattered out in the fall it might be manured, and, when large enough, thinned out, and thus kept as a constant crop."

In the Journal of the Royal Agricultural Society of England, vols. 4 and 5, we find some account, by George Jesty, of the culture of mustard for fodder, or preparation for crops, which seems to prove its value for these purposes. He says that it is good both for cattle and sheep. The white species is that which he employs, as it is not liable to remain in the land after it has been once ploughed up, as the black will. A Mr. Hale, who was induced, by Mr. Jesty's success, to try it, says he sowed his on light, thin surface soil, subsoil white chalk, which had previously been cropped consecutively, as the two last crops, with wheat and oats. He states that he made a clean fallow with thrice ploughing, &c., and, *without* manure, sowed broadcast sixteen pounds of mustard on the 22d of July; and, "on the 2d of September, six weeks from the day of sowing, (scarcely a drop of rain during the whole period,) folded it off with about 300 ewes. On commencing the fold, the ewes did not appear to relish it; but on the following morning every stalk was eaten bare to the ground; and, even after, it was consumed as quickly and eagerly as any other green crop." He next tried it in comparison with rape, to be fed off by sheep, and as a preparation

for wheat. The experiment was in favor of the mustard, as the produce was considerably more than the rape; giving more nutritious food, and full three weeks earlier in its growth.

Mustard is also cultivated for its oil. The amount produced, according to Veit, is 12½ pounds for a bushel, or 30 pounds for 100 pounds of seed.

A better oil plant, however, and one which may be worthy the attention of our agriculturists, is the *colza*, of which there are two varieties, the summer and winter. An account of this plant, together with a treatise on the method of culture, translated from the French by J. W. P. Lewis, of Boston, will be found among the papers furnished by Mr. Ellsworth, and referred to by him in his letter to the Commissioner of Patents, appendix No. 1. Mr. Lewis also received from France some of the seed, which has been distributed from this office, and it is hoped that many a successful trial will yet be made to introduce it into this country's list of products. The oil is said to be so fine that it is used in the French light-houses, as well as for various other purposes. In Thaer's Principles of Agriculture, (now publishing in the Farmers' Library and Monthly Journal,) will be found a full account of the modes of culture, &c., as practised in Belgium, taken from Schwertz's Belgian Husbandry.

Another *oil* plant which is highly recommended is the *madia sativa*, a native of Chili, from which it is said an oil may be extracted superior to the olive oil. Mr. Boussingault gives the following statement of an experiment made by himself in cultivating the *madia sativa*, intermixed with carrots, in a fertile soil, well manured with farm dung. He says that it was an excellent crop. It took 127 days to come to maturity. The amount was—Seed, 2,424 pounds, husks deducted; dried leaves employed as litter, 7,700; carrots, without their leaves, 31,966. The seed gave—of oil 635.8; of cake, 17067.6. 100 of seed gave, of oil 26.24; cake, 70.72; loss, 33.4; total, 100. He says that this agrees with results published by others, but the seed which in the press gave 26.24 of oil per cent., actually yielded 41 per cent., by analysis, in the laboratory. In the Journal des Connaissances Usuelles et Pratiques, vol. 29, we find an article on the *madia sativa*, and its culture, &c., which has been translated and subjoined in an appendix to this report, No 18.

The *camelina sativa*, or *myagrum sativa*—gold of pleasure—(Leindotter of the Germans,) is likewise recommended for culture as an oil plant in some of the English agricultural journals. A writer in the Mark Lane Express, who tried it, says that he drilled in his seed on the 24th of March, in rows, nine inches from row to row. The soil was a strong loam or clay, prepared after beans. It grew most luxuriantly until the end of May, when he fed down three acres by sheep, leaving another three for seed. The sheep ate it most voraciously after it had been fed down; and, to his surprise, the plant shot up again, and produced a fine crop of seed. If the weather had been good, the harvest would have been three weeks earlier than it was in the latter part of July. He cut it with a sickle, the same as wheat, bound it in sheaves, put it up in rows till dry, then threshed it out. The quantity of seed from the three acres yielded 72 bushels, of 56 to 60 pounds weight each. The other three acres were not harvested at the date of his letter, (August 21,) but he expected a fine yield; and, after the crop, to prepare the land for wheat, as he felt convinced that it does not impoverish the land like most other crops. The straw, likewise, he mentions may be used by cutting it up into chaff, and thus an excellent food is produced of a

very nutritious nature, as the stalks abound in a gelatinous substance as well as the chaff; or, burnt into ashes, it makes manure; or, being small and durable, they make good thatching." He concludes by saying that there are so many valuable properties about it, it will prove unrivalled; the oil, the oil cake, (of a most nutritious nature,) the plenty of green herbage for sheep, all recommend it most highly. The oil cake he tried upon bullocks, sheep, and calves, and they liked it so much that he determined to have no other. He says that it is a fine herbaceous tonic; combined with mucilage, gluten, and gum, where the linseed is not.

In Lawson's Agricultural Manual, he says: "The gold of pleasure produces a finer oil for burning than the rape or mustard, having a brighter flame, less smoke, and scarcely any smell. It succeeds better than any of the other cruciferous oil-plants on light shallow dry soils, and arrives so soon at maturity that in the south of Europe it produces two crops in a season. In several of the more northerly districts of the continent, as the north of France, Germany, and Holland, although it will not produce two crops in the season, it is found very useful for sowing in June, or beginning of July, where other crops have failed; and when sown in the early part of the season, it may be removed, to be succeeded by turnips, grass, seeds, &c. Besides the use of its seed for oil, the stem yields a coarse fibre for making sack, sail-cloth, &c., and, being small, hard, and durable, are used for thatching temporary erections, and also for making coarse packing paper. A superior variety has lately been introduced into France, under the name of *la cameline majeur*, and which differs from the common in being of stronger growth, producing more seed pods, which contain a greater number of larger and more oily seeds. One circumstance deserving of attention is, that it is never found to be at all injured by insects." Boussingault gives the productiveness of the gold of pleasure, of oil 27 per cent., and of cake 72 per cent.

Thaer, in his Principles of Agriculture, also speaks of it thus: "This plant grows wild, and is sometimes very troublesome among flax. It grows to the height of one or two feet; the stem is angular, hairy, and branching; the leaves are lanceolate, and embrace the stem at their basis; the flowers are yellow, and grow in clusters at the top of the stem. The plants delight in sandy soils, provided they are rich; and it is on such soils that it is cultivated, but it exhausts them in a great degree. It is sown in April, and gathered about the end of July or beginning of August. It is less subject than other oil plants to the ravages of insects, and seldom fails entirely. Its produce scarcely exceeds five bushels per acre. [This is an evident mistake of the translator.] A bushel ought to yield from twenty to twenty-four lbs. of oil." Another author says that it has the peculiar advantage of ripening its seeds in the short space of three months from the time of sowing, and thus is sown in spring, when winter colza or rape has perished in the winter. The amount sown is said to be less than two pounds to an acre, mixed with sand to distribute it more equally; then it is harrowed by a bush harrow, and as it will grow on very poor land, it needs no more manure than was left by the last crop. With the stems brooms are made, and in some places it is cultivated for this purpose. Veit says that it is less injured than any of the other oil plants by frost, drought, or wet weather. In seed he states that it yields two to three schäffel (a schäffel, Bavarian, is nearly 6¼ English bushels) per morgen—about 0.842 of an English acre. He says that it yields 28 pounds of oil and 66 pounds of oil-cake out of 100

pounds. Professor Burger, also, of Vienna, gives a similar account of the gold of pleasure, which we here translate. He says: "The gold of pleasure (*myagrum sativum*) deserves the highest regard for a loose sandy soil, deficient in *humus*, and in which the other oil plants do not thrive, because it does not suffer on account of dryness, is not attacked by insects, and yields, in the given circumstances, a fair crop. This plant has been planted often in lower Carinthia, along the Drave, in bad sandy fields, filled with stones, but it is rarely found in deep loamy and fruitful soils, although there greater harvest may be expected. I think, after numerous observations made for many years, in different localities, on the success of the plant, that it particularly agrees with a not too loose sand soil in a warm and dry climate. A field which has been manured during former years is most suitable to it. It may be sowed at any time during the spring, since it is not much injured by dryness, and is of rapid growth. It is also suited for a late sowing, although the earlier is always most preferable; from March to the middle of May is the proper time with us, (Austria.) It must be harrowed and hoed. On an average it yields 12, and in the most favorable circumstances 18 metzen for a yoke, or 20 to 30 bushels for about 1½ acres. A metzen of seed weighs from 75 to 81 lbs., and yields 18 to 24 lbs. of oil."

The cultivation of the *castor bean*, also, for its oil, is gaining ground among us, and promises to reward the industry of those who turn their attention to it. The American Farmer for May 14, 1845, contains an account, taken from the Southern Whig, of an experiment to this effect made in Georgia by Mr. Joshua Willis, of Troup county, which we here subjoin: "During the past year he manufactured about 1,500 gallons of oil, which was mostly, we believe, purchased by the druggists and physicians of Columbus and the circumjacent country. We were favored with a specimen of the article referred to, and cannot but regard it as a fair and beautiful oil—almost destitute of color or smell, and as little of the unpleasant flavor peculiar to the castor oil bean as is consistent with an unadulterated preparation. Clear, bland, free from rancidity, and without any foreign admixture, it constitutes an admirable article for domestic use, and, in our hands, manifested mildly but effectually its cathartic property. The East Indies have heretofore furnished probably seven-eighths of all the oil consumed in England; but for the last several years American oil, derived chiefly from the British colonies and the western States, has been exported to that country to the amount perhaps of from fifty to eighty thousand pounds annually. The latter article, though confessedly of fine quality, and possessing a flavor superior to the East India oil, has yet been regarded as objectionable on account of the deposite (in cold weather) of a white flaky matter, which some have supposed to be *margaratine*—a fatty salt, consisting of the two proximate constituents, *margaratic acid* and *glycerine*. Others have supposed it to be the result of adulteration from olive oil, which is known, at low temperatures, to deposite what Pelouze and Soudet regard the *margarite* and *oleate of glycerite*, (the hydrated oxide of glycerine;) an unlikely supposition, however, in our estimation, as most of the latter oil is imported into this country from the south of Europe, and at too high a price to warrant the fraud of admixture with the castor oil designed for exportation. We are rather inclined to the belief that such deposite, so frequently found in the American article, is from the liberal mixture of animal oil, (*Adeps suillus*,) which does not sustain its fluidity under from 78.5

deg. to 87.5 deg. This may perhaps account for the rancid and acrid nature of some of the castor oil of commerce, as the olein of the lard readily becomes rancid; *i. e.* acquires a disagreeable odor and acid properties by exposure to the oxygen of the atmosphere. Indeed, the deposite of *margaratine* from castor oil, if any, should be exceedingly small, as not more than 0.002 of the entire products of saponification consist of margaritic acid. The oil manufactured by Mr. Willis, we believe, fully sustains the truth of this last remark, and, as a specimen of southern enterprise, alike honorable to his skill and industry, and commends itself to the public confidence and popular use. Mr. W. will be prepared to execute large orders this fall and winter, and assures us that it shall not cost, to druggists or other purchasers whom he may supply, more than the best article does from any other quarter; and all he asks is, that, other things being equal, home manufacture may have the preference."

Again: The following calculation may aid those who wish for further information respecting this product: "*Castor beans.*—A friend, who has statistical information with respect to the production of the castor bean, and the manufacture of the oil, handed us, a few days since, the following calculation, which we cheerfully publish, trusting that the farmers of our vicinity will look to the enterprise and test its efficiency: Say 40 farmers plant 20 acres each; 800 acres, at 35 bushels per acre, would yield 28,000 bushels; 28,000 bushels, at 50 cents per bushel, would amount to $14,000; 1,225 barrels cost $1 each, $1,225; freight to New York, at $1 50 per barrel, $1,838. Charges for insurance, &c, &c., $1 per barrel, $1,225. Two hands to make oil, say $512. Total of expenses, $18,800. 28,000 bushels of beans will yield $1\frac{3}{4}$ gallons oil per bushel; 49,000 gallons in all—at 60 cents per gallon, $29,400. Deduct expenses, $18,800, and the 40 farmers, with 20 acres each, would realize the handsome profit of $10,600. This may be considered figure work, and an easy way to speculate on paper; but we hope the experiment will be tried by our enterprising neighbors."—*Lexington (Missouri) Express.*

The castor oil bean, it is said, will yield 60 per cent. of oil, which is a larger proportion than most of the oil plants.

A plant called the *bene* plant (*Sesamum orientale*) is also highly recommended, on account of the large quantity of oil which it contains. It is derived from the West India islands, where it was introduced from Africa, and is somewhat known in the southern States. The letter of Mr. Merriam to this office contains a description of it.—(See appendix No. 19.) It is said, likewise, to be possessed of valuable medical virtues. It seems, from Mr. Merriam's account, that the oil is light colored and flavorless; but it contains too much mucilage to make soap. In the Farmers' Cyclopedia we find an account of this plant, in which it is stated that the oil pressed from its seeds will keep many years without acquiring any rancid taste; but in two years becomes quite mild, and can be used for sallads, &c. Nine pounds of the seed are said to yield upwards of two pounds of fine oil.

"It is described to be an annual plant, growing like cotton, three to six feet high, with numerous square pods, about $1\frac{1}{2}$ inch long, filled with seeds about the size of flax seeds. The product is about 12 or 15 bushels per acre, and the proportion of oil yielded to the pressure has been estimated as equal to half the measure of the seed;" and by some in still greater proportion. It is sown in April, and gathered in September.

A plant of the cabbage or colewort species—also used, indeed, as a vegeta-

ble—is the *broccoli*, which we mention here for the purpose of directing those who may feel interested to learn respecting its culture to the paper prepared by Dr. Junius Smith—the same gentleman to whom the office was indebted, in the report of the preceding year, for his valuable remarks on the cultivation of celery. His modes are based on actual experiments, and are entitled to attention from his long acquaintance, by his residence in England, with the best methods adopted there for raising many of the garden vegetables. (See appendix No. 20.)

The *coloring* plants are also worthy of notice—especially *madder* and *indigo.* Each of these topics were adverted to in the last report. Since then, we have observed some articles published in the agricultural papers, which appear to furnish some additional valuable information; and we therefore have placed them in an appendix, No. 21. The communications of Messrs. Winifree, Partridge, and Spalding, in the American Agriculturist for November, 1845, and February, 1846, are full of interesting particulars respecting the preparation and culture of indigo. That it affords a favorable object towards which the enterprise of a portion of the south might be advantageously turned, scarcely admits of a doubt. The great object seems to be, to recover the lost method of preparing the article for market.

Mr. Boussingault states, that in Venezuela those soils were preferred for indigo which are light, and susceptible of irrigation—a condition which he pronounces all but indispensable to profitable cultivation between the tropics. Indigo, he says, "requires a warm climate, at an elevation of about 3,250 feet above the level of the sea; where the mean temperature is not more than from 72° to 75° Fahrenheit, the indigo husbandry cannot be carried on to advantage." "In the valley d'Aragua, where the best plantations are met with, the plant is sowed in lines—the holes destined to receive the seed being about 1¾ inch in depth, and somewhat more than 25 inches apart. A pinch of seed is dropped into each hole, and is covered with a little earth. The sowing takes place in soils that are moist but well drained, or in situations generally which have no system of irrigation at the period of the first rains. The seeds shoot in the course of the first week; hoeing is performed in the course of the month. The first cutting takes place when the plant is coming into flower; from 50 to 60 days generally intervene from the sowing to this cutting; but the time necessary for the development of the leaves depends, of course, upon the climate." Near Maracaibo, where the mean temperature is about 78° Fahr., the gathering does not take place before the third month. The second cutting is performed from 45 to 50 days after the first, and in this way several successive crops are obtained, until it is seen that the plant begins to degenerate. In good soils the indigo will last for two years; in soils of an inferior quality, the crop is generally annual.

"The indigo harvest is immediately transported to tanks, or large rectangular reservoirs, built of masonry and disposed on different levels, the superior or steeping tank being much larger than the two others. Some in the valley d'Aragua," he says, "are upwards of 20 feet long by 15 wide, and 20 inches deep. The second or mashing tank is narrower and deeper than the former. The third, or depositing tank, receives the liquor from the mashing tank, and there the indigo subsides. Some do not use the third tank, but have the deposite take place in the mashing tank. The leaves are thrown into the steeper, covered with water, and kept down by planks loaded

with stones; fermentation soon begins, and is allowed to continue for about 18 hours."

"It is in the management of this first operation," says M. Boussingault, "lies much of the art of the indigo maker. If it is too long continued, some part of the coloring matter is destroyed, and by stopping it too soon the indigo is left in the leaves. When the fermentation is judged to have gone on long enough, the liquor is run off into the battery and vigorously stirred until the *grain* is deposited. The fluid is then either let into the subsider or left in the battery, and the deposite is complete at the end of about 20 hours; the fluid floating above is drawn off, and the indigo paste is scooped out and placed on cloths to drain. When firm enough it is divided up into lumps, and these are set in the shade to dry. The product in the valley d'Aragua is, in good soil and with care, 280 pounds per hectare, or about 112 pounds per English acre. In Carolina it is not as productive, &c. In the East Indies, on the Coromandel coast, the growth of indigo takes place on sandy soils which are not irrigated, and in which vegetation is only possible during the rainy season. Immediately after rains have set in, in December, the land is ploughed twice superficially, the indigo is sown broadcast, and the seed harrowed in by dragging a fagot of bamboos over the surface, or treading it in by a flock of sheep. The first and principal gathering is in March. Any other crop is purely casual, and depends wholly on the rain that falls. The drought, so frequent on the coast, affects it. The harvest takes place after the flowering season. The crop is dried in the sun; the plant is then beaten with switches, and thus the leaves are detached from the stems; after which, to make them perfectly dry, they are again placed in the sun; when they are reduced to coarse powder, and hauled over to the indigo manufacturer."

"On the coast of Coromandel," says M. Boussingault, "the indigo is always extracted from the dried leaves; which, bruised and broken, are steeped in three or four times their bulk of cold water for two or three hours. The indigo is then filtered through a loose stuff made of goat's hair; the filtered liquor is beaten for two hours; then five gallons of lime-water are added for 100 pounds of dried leaves; the mixture is stirred, and left to settle. When the deposite is formed, the water on the top is drawn off; the sediment is washed in a little boiling water and thrown on a cloth, dried and drained. Then it is pressed and cut into lumps, and thoroughly dried in the air. In this process there is no fermentation. This indigo is not much esteemed in commerce; it is heavy, of a pale blue, rough when broken, &c."

In the Polytechnisches Archiv for 1841, mention is made of experiments to produce indigo from the Polygonum tinctorium. The Societe d'Encouragement, &c., in France, offered a premium in reference to this object, and some indigo of a fair quality was produced. The per centum of indigo in the plant, however, is so small that there seems little reason to expect any productive results from its manufacture from that plant. Boussingault, in his Rural Economy, says: "This plant is a native of China, and was brought to France and propagated under the care of M. De Lille. In the course of three months it has thrown out all its leaves, and in the south of France it never fails to ripen in the seed. From some experiments that have been made, the leaves of the polygonum appear to contain about the five thousandth of their weight of indigo; and as the acre of land will yield between 11,000 and 11,900 pounds weight of leaves, the produce of the coloring matter will come to upwards of 56½ pounds." M. de Vilmorin

proposes to reduce the colored and insoluble indigo to the colorless and insoluble state, by means of a salt of the protoxide of iron in contact with an alkali, and subsequently to restore its color and effect its precipitation by contact with the oxygen of the air. M. Boussingault says that this would undoubtedly be a great improvement. As we are speaking of dye plants, we may here say, that it is stated in an English journal that the outer case of the *balsam* affords a beautiful orange dye, and it is suggested that the cultivation of this plant may be an object worthy of attention.

One of the agricultural journals thus speaks of the subject of indigo and madder as articles of culture, which deserve notice, in view of the over-production of cotton in the southern States. The suggestions are valuable, and there can be but little doubt that either of the products may be so cultivated as to prove a remunerating one: "Among the *new* articles of product which we have seen recommended to the adoption of the southern planters by the southern press are those of indigo and madder, both articles of vital importance to the manufacturing interest, and each offering in itself, to a very large extent, an encouraging reward for a large amount of labor now but indifferently paid for. Of *madder*, there are consumed in dyeing at least a million of dollars a year, and we should presume that the value of *indigo* used in the same way would amount to an equal sum; so that, if these estimates be placed upon proper data, these two articles alone will enable southern planters to substitute the culture of them to that extent for cotton; and thus, by diverting so much of their soil and force from the production of cotton, they may effectuate a threefold good: First, decrease the product of cotton to the standard of demand; second, re-establish an equitable value for it; and, third, procure a just reward, in the price of indigo and madder, for the surplus labor of their plantations."

In the New York Farmer and Mechanic for March some mention is made of a discussion on the subject of madder in the New York Farmers' Club, in which it is stated that, as near as can be ascertained, the last year's importation (for 1844) was about $1,800,000. The British import of madder in 1839 was about 20,000,000 pounds; in 1841, 27,000,000; in 1842, 20,000,000. British duty 2 shillings a hundred pounds on ground madder, and sixpence on raw madder. The price varies from 14 to 17 cents per pound. It is further said that, as it must be mowed to give growth to the roots, the leaves will make a fodder nearly equal to lucerne. The extract of madder is called *garancine*. It is stated that in the calico printing works in our country there are printed weekly 166,000 pieces, or 8,632,000 pieces per year, (the average price 6 to 8 cents per yard;) which gives, at $2 per piece, $17,264,000. Were all these establishments working to their full ability in what are termed *fast-color prints*, each piece of which needs from 1 to 3 pounds of madder, it would reach to 5 or 6 thousand tons weight—in value over $2,000,000. But as fast colors are not used in half, estimating them at 75,000 pieces, requiring 1½ pound each on an average, there will be consumed nearly 6,000,000 pounds a year—amounting, at 17 cents, to $1,000,000; to say nothing of its use in dyeing, or for various other purposes. No substitute has yet been discovered for permanently fixing the colors, so that madder must be considered essential to the calico printer. It will be seen, therefore, that there is much encouragement for its culture to supply our own market; and as the British duty is only about one-half farthing per pound, it may be profitably exported.

It is stated in the American Agriculturist that during the year 1845

10,000 bags, equivalent to 700 tons of *sumach*, nearly one-twentieth of the home consumption, have been sent from the south, principally from Virginia. The writer says that such as can be raised in South Carolina, Georgia, Alabama, and more particularly Florida, would be of better quality. It should be gathered as soon as ripe, and planted soon, so as not to become too old. This is said to be an important fact for southern planters; for by planting the seed, and mowing down the shoots three times annually, they might obtain from 3 to 5 tons per acre, with much less expense and trouble than by gathering and bringing home the natural growth, scattered extensively over the country. The sumach is perennial, and when once planted would last for ages; the crop, when sown, annually increasing, until the ground becomes full of roots. In the same journal for September, 1843, may be found an article on the cultivation of sumach, with the time for cutting, and modes of preparing for the market.

While speaking of products the culture of which may be tried in our country, it may not be unworthy of notice to allude to the following statement, which we find in the London Gardeners' Chronicle for November 1, 1845: "The French, in despair of getting genuine attar of roses, which is always excessively adulterated, have taken to searching for a substitute, and seem to have found one in *Pelargonium capitatum*. We learn that M. Demarosn has tried the experiment of cultivating this plant in the open air, in a loamy soil. He planted 100 rods with 5,000 cuttings; they grew fast, and in October he gathered the crop, which amounted to from 4 to 8 pounds of leaves and stems each plant. When distilled, the product of essential oil was much larger than could be obtained from roses, and the water was found excellent for perfumery. The quality of the articles prepared from this essence was considered by the best judges to be far superior to that of roses in their present state of adulteration. In short, the experiment was so successful and profitable that it is about to be repeated on a large scale."

In the last report mention was made of *spurry* as a product which might be useful in this country. In the Journal des Connaissances Usuelles et Pratiques, volume 29, we find a notice of a giant spurry, a translation of which we subjoin in an appendix, No. 22.

The subject of *artichokes* was also noticed in the last report; and we may here add a statement which was published in the American Farmer for November, 1845, from Mr. S. Weller, of Brinkleyville, North Carolina. He is speaking of the field culture, and he says: "To the use for stock generally, and swine in particular, I invite the attention of planters. I selected a spot of very moderate fertility, which some would call poor land; and after running furrows about 3 feet apart, I put in the drills, ere planting, a few old cornstalks by way of manure, then dropped bits of artichoke about 10 inches apart, and covered them with the plough. The after culture was very little, as that of scarifying the ground with the harrow and cultivator 2 or 3 times, and giving very little hoe work. They grew very luxuriantly; and in the beginning of winter the furrows, where the plants were, were opened, and the artichokes gathered, are all appearing in the drills. I filled several empty flour barrels, and those thus saved kept perfectly sound, in a cellar, till spring, when some were planted, and the rest fed to swine; and in the ground where the first patch was planted, early last spring, the young plants came up as thick almost as they could stand. All but the few in the drills were dug up and fed to my hogs. Having seen accounts in the Cultivator of one gentleman in Alabama, and another in Massachusetts,

who each made about 700 bushels to the acre, I was desirous to ascertain the yield of mine as near as I could, and made out 20 bushels on the twentieth of an acre, or that the yield of my poor ground was not much more than half of the two named north and south. But I was so much encouraged by the result, that I planted nearly two acres last spring, in lots where I can keep my swine in the winter. I have just given these their last working, and they all look very promising. The severe dry spell here has affected them less, I believe, than any other field culture vegetable. There are some striking advantages in artichoke culture. One is, their great and sure yield, compared with that of most other plants. For instance, I consider their produce ten times greater than that of corn, and with far less labor in the culture. Again: they keep perfectly sound in the winter in almost any situation, either gathered or left in the ground. If the latter, hogs can help themselves at any period after the crop is matured, till they are again cultivated. The tops (an abundant yield of them too) are good for stock, (green or cured,) or they are valuable to put in the drills for a succeeding crop, and tend to thus improve the soil where cultivated—on the principle that the litter or tops of any vegetable is the best help in the way of manure for that vegetable, as cornstalks put in drills is the best litter for corn, as I have found from several years' experience. Where the artichoke tops were in the drills this year, I find the most. I have lately learned that a gentleman in Nash county brought a very superior kind of artichoke from Tennessee, and that the yield and growth are truly astonishing; and that so anxious are his neighbors to avail themselves of its advantages that they gave him $2 a bushel for seed. I have been told, from the same source of information, that the Nash farmer has a field of 20 acres now in culture, and that the tops are higher than a man's head. If so, they are rather higher than mine are now. I shall certainly, if I live, try and procure a bushel for seed of said kind, if for no other reason than to compare with my indigenous variety; and if found superior, or answerable to the stirring description of the Tennessee kind, I shall communicate the fact for your useful print in due time."

Such facts as these, taken in connexion with such as have been mentioned in former reports, seem sufficiently conclusive as to its utility as a product for cultivation.

The cultivation of *arrow-root* seems to promise success in Georgia. A notice to this effect appears in one of the public journals. "*Georgia arrow root.*—We have received from Col. Hallowes, of Camden county, a very superior specimen of arrow-root, of his own manufacture. Col. H., we are pleased to learn, is extensively engaged in the culture and manufacture of this article. His preparations for separating the powder and drying it are extensive and costly. He has been entirely successful, and now offers for sale between 4,000 and 5,000 lbs. as the result of his last year's operations. Col. H. warrants it not only to be entirely free from all impurities, but also to be decidedly superior to the imported article."—*Savannah Republican.*

In appendix No. 23 will be found an interesting statement of the profits of cultivating *locust-timber.*

As to the products of the *dairy,* which were noticed in former reports, we have gathered some interesting extracts from the agricultural journals, both of our own country and those of England, some of which we shall embody in these pages, and refer for others to the appendix No. 24, on these subjects.

The preparation of *butter* has become an object of greater interest to our farmers now than it was formerly—as much now depends on this to secure its introduction into the foreign market. In the Mark Lane Express we find an account of the English method of preparing butter for the London market, which may deserve the attention of those who have begun to export the products of their dairy to that country. "The following is the most approved method of making and preparing butter for the London market, and is submitted for the advantage of farmers and dairymen throughout Ireland. Butter made on this system, with care and quick despatch, will insure high prices and quick returns. * * * The best land is old pasture, as free from weeds as possible, with abundance of good water. The cows should not be heated or tormented in any way, housed at night, and fed on green food, and the pasture changed when practicable. In milking, take saltpetre in the pail, one eighth of an ounce to eight quarts of milk. The dairy should be perfectly clean; airy; of equal temperature, say 50°; very little light, and completely shaded from sun by trees or otherwise; and in winter a stove may be required. Strain the milk into coolers, sweet and dry, (never mix warm and cold milk,) keep it from two to four days, then put the whole of the milk and cream into a clean churn, which is not to be used for any purpose except during the time it is in operation. Boiling water to be added to raise the temperature to about 68°, or 60° if horse or water-power be used. The time occupied is from one to two hours, depending on the size of the churn; but churning should not be continued beyond the proper time. After churning, put the butter into two bowls or pans of pickle, made from pure water and fine stored salt, (as common gives the butter a bad flavor.) It should be well washed, and the pickle changed frequently, until all milk is extracted. working with the hand the two pieces alternately until the grain becomes quite close and firm, when it is to be cured with the finest dry stored salt and sugar. The proportion to be one ounce of refined sugar to one pound of salt, to be well worked into the butter with the hand; but the quantity of curing materials will depend on the time and labor given by the dairy woman in working and beating the butter, (after the salt and sugar are applied,) which should continue until all pickle is driven out. The butter should be finished the day it is churned, and then be pressed as closely as possible into the cask. The cask should be well seasoned for some days previous, with strong pickle, frequently changed, or hot pickle, and must be strong and air-tight; the size is of no consequence if filled and sent off in one week. If not filled at one churning, the butter is to be covered with pickle until the next; but no cask to contain more than one week's butter. If butter should at any time appear pale in color after churning has commenced, a little grated carrot juice may be put into the milk, and will not injure either milk or butter. All butter should be at the place of shipping one day prior to the steamer leaving, so as to run no risk of going forward to the agents."

The Ohio Cultivator gives a communication which furnishes the Russian mode of making butter, as follows: "*Russian mode of making butter.*—I have for several years had the entire care of the milk department in my father's family. I therefore read with great interest whatever related to making butter and cheese, and I found much that was different from what I had been in the habit of practising. One case of this kind was directions for making butter in winter, according to what is called the Russian

method, by which it was said that butter could be made in winter as sweet, and with as little churning, as in summer. So I set about trying the experiment, and the result exceeded my expectations. My new practice is as follows: Before I go out to milk, I put a kettle, say one-third full of water, and large enough to let the milk-pail into it, on the stove, where it will get boiling hot by the time I have come in with the milk. I then strain the milk into another vessel, and wash the pail, which should always be of tin; then pour the milk back into the pail, and set it into the kettle of boiling water till the milk becomes scalding hot, taking care not to let it boil; then pour it into crocks or pans, and set it in the cellar for the cream to rise, in the usual way. As little time should be occupied in this heating process as possible; hence the advantage of having the water ready hot when the milk is brought in. Cream procured in this way will seldom require more than twenty minutes' churning, while, by the common practice, the poor dairy maid may have to churn for hours, and then perhaps have to throw it away, as I did myself on two occasions, before I happened to gain this valuable piece of information."

A mode of making butter by means of an atmospheric churn has been recently stated to have been invented in Ireland by the Bishop of Kildare. The results are said to have been in the highest degree satisfactory. The results of the process are ascribed to the oxygen of the air. It will be seen, however, from the subjoined extracts from the proceedings of the Farmers' Club, in New York, that something similar is affirmed to have been discovered in this country. A mode of working butter, which is said to answer well, will also be found in appendix No. 24.

"*New York, December* 10, 1845.—Sir: Three years ago last summer, I was trying a new method of cooling milk, being in the great milk business carried on on the Erie railroad. To cool the milk, I used an air pump to draw air through a reservoir full of ice, and force it into a receiver under a pressure of 50 lbs. to the square inch. Thus compressed, the air remained, the receiver being surrounded by ice to keep it cool. To this receiver a small pipe was attached, one end of which could readily be inserted in a can of milk, and the cold compressed air could thus, by means of a cock, be let at pleasure into the milk when we desired to cool it. The milk in these cans, in hot weather, being often very warm, and the air in the receiver having become warm for want of care, I found that the top of the milk was covered with butter, and raised cream in a few minutes. I saw that the churning was going on, and I had to stop my process. I mentioned this fact to the officers of the Institute at that time. I then proposed to patent it for butter making, for cooling, or, by my process, for steaming milk, (scalding it.)

THADDEUS SELLECK."

"*New mode of making butter.*—The Lord Bishop of Kildare states, that 30 years ago he had formed the idea of a butter churn on a new principle, but had not carried it into experiment until within a few weeks past. He states that his churn is made of tin, and this fits into another tin cylinder provided with a funnel and a stop-cock, so as to heat the cream to the proper temperature. He has a forcing pump, with a glass tube, through which he forces atmospheric air in full current through the cream at nearly the bottom of the churn. The pump is worked by a hand-winch. The experiments are as

follows: September 23—15 gallons and 2 quarts of cream, operated on for 2 hours and 10 minutes, gave 26 lbs. of delicious butter. September 26—10 gallons and 2 quarts gave, in 2 hours and 10 minutes, 23 lbs. of butter. September 30—12 gallons and 2 quarts of cream, in 2 hours and 10 minutes, gave 20½ lbs. of butter. October 3—10 gallons and 2 quarts, in 2 hours, gave 21½ lbs. of butter. October 14—10 gallons and 2 pints of cream, in 1 hour 45 minutes, gave 22 lbs. of butter. The next Friday 11 gallons of cream, in 2 hours, gave 26 lbs. of butter. The different results are ascribed to different temperatures and different qualities of cream used. The Bishop ascribes the results, by this process, to the intimate introduction of the oxygen of the air."

Cheese is another product of the dairy. The English ascribe the inferiority of the Dutch cheese to their own, in flavor and richness, to the Dutch method of soiling their cows always in the house; and assert that cut food does not answer as well for cows as natural pasturing. The subject is one of considerable interest, whether the theory just given be the true one or not.

We have also inserted in appendix No. 24 several valuable articles taken from various journals on the subject of cheese making, &c. Among these we may refer to the method of making Cheshire cheese—the mode adopted in cheese making by Mr. Fish, who gained the first premium of the New York State Agricultural Society for 1844—and the account of the Connecticut cheese dairies, &c., in the Cultivator, &c. We select a few of the notices which are frequent in the public journals, and which indicate the extent of the manufacture of butter and cheese in parts of our country.

"*Vermont butter again.*—A Vermont trader came to the city last week to sell his full supply of butter—90 tons! Pretty well for a single trader in a small town among the mountains."—*Boston Traveller.*

"*Cheese.*—The town of Collins, Erie county, New York, made 554,000 pounds of cheese during the last year. The town of Fairfield, Herkimer county, made 1,355,997 pounds during the same period. Herkimer county turns out, annually, 8,208,796 pounds of cheese. This, at eight cents per pound, (the present price of the article) would give the dairymen of old Herkimer $656,703 68."

As to our cheese abroad we find the following, taken from the English papers, by which it will be seen that the export has greatly increased within a few years—quadrupled within three years:

"*American cheese.*—On the motion of Sir P. Egerton, one of the members for the county of Cheshire, a return has been laid upon the table of the British House of Commons relative to the importation of foreign cheese, which exhibits the following figures:

		From Europe.	From America.	Total.
1841	-	254,995 cwt.	15,154 cwt.	270,149 cwt.
1842	-	165,614	14,098	179,712
1843	-	136,998	42,312	179,310
1844	-	160,654	53,115	213,769

"By this statement we find that the importation of American cheese has quadrupled during the last three years; and, during the last year, the importation amounted to 53,115 cwt. To our American friends we say, send nothing to this country but a good article; introduce more color into it;

and we are sure that, in another year, England will use four times the quantity of its previous consumption. We shall also be pleased to find that the manufacturer and exporter get a larger share of the prices for which it is sold in England. The writer of this has now upon his table an American cheese, equal to the celebrated 'STILTON,' for which 25 cents per pound is obtained; whilst this excellent '*American*' is sold for 13 cents only!!"—*English paper.*

With reference to the above, we may adopt the words of one of our own writers on this same subject: "Thus we are put in possession of the fact that excellent American cheese is sold at 13 cents per pound, (at which comparatively low price it will pay the shipper a profit,) which is in all respects 'equal' in quality to the 'celebrated Stilton,' which commands 25 cents per pound. The inference is very plain to us, that if the suggestions of the above writer are followed, this disparity in price between the two kinds will not continue long; and that, as American cheese becomes more extensively known in England, the demand for it will be increased, and consequently better prices for it will be obtained. Indeed, we believe the time is not far distant when England will be the great market for the product of our dairies."

Some other cheese statistics may likewise be interesting in this connexion.

"*Cheese statistics and speculations.*—We take from the Rochester Democrat the following statistics of one of the staple articles of the country, to which we add some remarks and facts of our own:

"'A new impetus seems to have been given to the cheese trade, and for a few weeks it has been in great demand for the eastern market. About six weeks since speculations in the article commenced in Boston; and a few days after, the bulk of the quantity in that city and New York was monopolized by a few dealers. The price going up east, a house in this city went into the market in this section of the State and bought up nearly all that could be found in this and the adjoining counties, and forwarded it to Boston. What was dull sale last fall (at the close of navigation) in the eastern cities, at four to five cents, is now in demand at seven to eight and a half cents—the rise being nearly 100 per cent.

"'The rapid increase of this important item of the dairy at the west is astonishing. Last year the aggregate value of the amount that passed through the canals and the Hudson river was over $1,500,000.

"'We gather the following interesting statistics in relation to it from the canal office at Albany. Arrived at the Hudson river—

1834	6,340,000 pounds.
1835	9,586,000
1836	14,060,000
1837	15,560,000
1838	13,810,000
1839	14,530,000
1840	18,820,000
1841	14,170,000
1842	19,004,000
1843	24,334,000
1844	26,677,500

"'The shipments to foreign nations have averaged, for the last ten years, about 3,000,000 pounds annually. This went to forty two countries. With-

in the two past years the market in England has been gradually gaining, and there was exported there in 1843, 2,253,416 pounds—1844, 5,000,000 pounds estimated.

"'The last accounts from Liverpool state that the American cheese was driving that from Ireland out of the market. The West Indies and Cuba are our next largest foreign markets. China, it is supposed, will also be our customer, large quantities having been sent there as an experiment.

"'During the past winter about 400,000 pounds have arrived at Albany by railroad. Of this amount, not far from 100,000 pounds were sent from this city.

"'We notice by the Cincinnati prices current that it is scarce in that city at seven and a quarter cents—the market having been mostly cleared by a New Orleans house for a foreign market.

"'At the port of Cincinnati, in the year 1844, there arrived the following amounts and value of cheese: Cheese in boxes, 74,073—2,590,000 pounds; cheese in casks, 2,968—509,400 pounds. Total, 3,099,400 pounds.

"'This was sold at an average of five cents per pound, making about $156,000 for the article of cheese; which, when we look at it on the table, appears to be a small matter. About five millions of pounds are also transported on the Pennsylvania and Ohio canal from the counties of Trumbull, Portage, Summit, &c., &c.

"'Cheese, then, is a very extensive article of trade; and it is a very important fact that the export of it to England doubled the last year. At the present prices the export of cheese to England amounts to $300,000. This is quite an item in our accounts.'"—*Cincinnati Chronicle.*

We may also add the following milk statistics of the amount of milk forwarded to New York over the New York and Erie railroad for 1844: January, 208,156 quarts; February, 206,656; March, 300,088; April, 434,546; May, 604,166; June, 646,896; July, 750,186; August, 651,188; September, 554,826; October, 497,772; November, 429,784; December, 326,132. Total, 5,611,016. The amounts of the first two months in 1845 were—for January, 300,840; February, 276,286.

It is often desirable to destroy the leeky taste of milk or butter. We notice the following is stated to be effectual: "We are informed by Mr. Dennis Rust, of this place, who has tried the experiment, that one teaspoonful of pulverized saltpetre, put into three gallons of milk, will entirely destroy the taste of leeks or ramps. Butter may be purified by the same process."—*Laporte Whig.*

Boussingault states, in his Rural Economy, that from 100 lbs. of milk he obtained—cream, 15.60; white curd cheese, 8.93; whey, 75.47; total 100.00. The 15.60 lbs. of cream yielded, by churning—butter, 3.33, or 21.2 per cent.; buttermilk, 12.27. And the milk, 100 lbs., thus yielded of cheese 8.93; butter, 3.33; buttermilk, 12.27; whey, 75.47. He states that for the whole of the milk obtained and experimented on at different seasons, being 36,000 lbs., he found that it yielded 1,080 lbs. of fresh butter, which it at the rate of 3 per cent.

In France: "M. Dumas read the first part of an interesting paper on the nature of the milk of different animals. He observes that the milk of herbiverous animals always contains four orders of substances which form part of their food, viz: the albuminous, represented by the caseine; the fatty substances, represented by butter; the saccharine portion of their food, represented by the sugar of milk; and, finally, the salts of different kinds which exist

in all the tissues of these animals. In the milk of carniverous animals there is no sugar, and there are only the albuminous, fatty, and saline substances which form the general constituents of meat. If, however, bread be added to the food of these animals, the sugar of milk will be found, although not in large quantities. M. Dumas concludes his paper by stating that his investigations have enabled him to arrive at a perfect analysis of milk."

In an article in the Cultivator of August, 1845, furnished by C. N. Bement, of Albany, on the quality of milk, he says: "An ordinary cow fed on young clover should give, for the first three months after calving, from 15 to 18 quarts of milk per day; which will produce, if of good quality, one and one-fourth pound of butter, or nearly nine pounds per week. The excellence of a dairy cow is estimated by the quantity and quality of her milk, and the quality of the milk is estimated by the quantity of butter that it will yield. Much depends on the quality of food, but more on the animal. The writer has known one cow whose milk would not produce butter, and never was discovered while milked with the herd, but was soon apparent when separated and milked alone."

He speaks of the lactometer, or instrument for measuring the relative qualities of cream of the milk of different cows at different seasons of the year. It consists of a stand with six glass tubes, and these are graduated with tenths of an inch. The milk of six cows is poured in, and the number of degrees of the thickness of the cream indicates the quality of the milk of the cows, &c. He says, further: "In a trial of seven cows, six weeks after calving, in March and April, they varied from 13 to 7½ per cent. Out of the seven the milk of two produced, after standing 24 hours in a temperature of 40°, 13 per cent. cream—one 12, and another 11 per cent.; another, at 46°, 9 per cent.; while two at 42° stood at 8½ and 7½ per cent. The milk of four cows, mixed in a temperature of 48°, marked 11 per cent." He declares, that "by various comparisons the result was, that the average quantity of milk of a cow when kept alone greatly exceeded that of our best dairy herds, and the quantity of butter made from a given quantity of milk is also greater."

In the Comptes Rendus an instrument is mentioned for measuring the quality of milk, called the lactoscope, which was favorably reported on by a committee for the purpose, and led to considerable discussion, M. Arrago and others objecting to its utility.

In the Massachusetts Ploughman, we have the portrait of a native cow which yielded in one week 15½ pounds of butter. The quantity of milk in one week was 108½ quarts; the greatest number of quarts any one milking of this week 10 quarts. Her food during this trial week was, a pretty good pasture, not extra, two quarts of meal a day, (half Indian and half rye.) She drank nothing but water. One day's milk weighed 38 pounds. It took, as will be seen, a little over seven quarts of milk for one pound of butter. This must certainly be considered very rich milk.

Another cow is mentioned in a paper as belonging to Mr. Lathrop, of South Hadley, which gave 14 pounds 2 ounces of butter per week. She gave in June, 1844, 55 quarts per day—so says the account; but we think it must be some mistake, and that the 55 should be 35. She was of the Durham kind, and cost, seven years ago, $700. In the month of October she gave 35 quarts of milk per day, and 10½ pounds of butter per week.

In the reports of the Agricultural Society of Newcastle county, Delaware, we find also a statement of the productions of an extraordinary cow. In

one week she gave 175 quarts, and the butter made was $2\frac{1}{4}$ pounds per day, or $15\frac{3}{4}$ pounds per week. Her lowest milking is put down at 14 quarts; her greatest, when fresh, at 26 quarts. Her greatest yield of butter at $2\frac{1}{4}$ pounds; her lowest at one quarter per day; averaging 1 pound 10 ounces per day. This was a native cow, raised by Mr. John Jones, of Wheatland, Delaware, by whom the account is given; and he claims that his cow thus takes the lead of the extraordinary cow of Mr. Forrest, in England, which gave $1\frac{1}{2}$ pound of butter per day for four years. The last time the experiment was tried by Mr. Jones, was when his cow, the Yellow Flower, had been giving milk four years, or since the birth of her second calf.

A cow called Kaatskill, which received the first prize of the New York State Agricultural Society in 1844, as the best dairy cow, belonging to R. Donaldson, Dutchess county, when kept on grass only, yielded $38\frac{1}{2}$ quarts of milk per day; and from the milk given by her in two days $6\frac{1}{2}$ pounds of butter were made, which is at the rate of $22\frac{3}{4}$ pounds per week. Her portrait is given in the January number of the Cultivator for 1846.

The greatest quantity of butter made by the celebrated Oaks or Danvers prize cow in one week, was $19\frac{1}{4}$ pounds; and the greatest quantity of milk in one day, 16 to 18 quarts. Col. Jacques's Creampot cow in three days gave 9 pounds of butter, which is 21 pounds per week. Six Durham cows of George Vail, of Troy, N. Y., made in 30 days 262 pounds 7 ounces of butter, which is an average of 43 pounds 12 ounces to each cow. The average quantity of milk per day for each cow was $22\frac{1}{2}$ quarts. They were fed on grass only. Others might be mentioned from Mr. Colman's list of 66 native cows, which gave large quantities of butter.

In one of his speeches in Ireland, Mr. C. mentions the Kerry cows, which are of a hardy race, and which give 320 pounds of butter in a season. Mr. Youatt, in his work on cattle, says: "The cow of Kerry is truly a poor man's cow; living every where, hardy, and yielding, for her size, abundance of milk of a good quality, and fattening rapidly when required."

The Ayershire cows, it is well known, possess similar characteristics; and in an account of a trial made between three Kerrys and three Ayershires, it is said the Ayershires gave rather the most milk; but the Kerrys exceeded them all in butter.

In an article in the Cultivator for March, 1845, headed "*Products of the Dairy*," we find it stated that the committee on cheese dairies of the New York State Agricultural Society reports Abraham Hall, of Floyd, Oneida county, as having made the past season, (1844,) from 40 cows, 23,427 pounds of cheese and 200 pounds of butter, an average of $585\frac{2}{3}$ pounds of cheese to a cow; and adding the butter, equal to 598 pounds to a cow. Mr. Fish, of Herkimer, made, previous to 17th September, an average of 592 pounds per cow; and he estimates the quantity for the season at 700 pounds. Mr. Porter, of Oneida county, from 12 cows and 3 heifers—one of them three, another two years old—made 2,600 pounds of butter for market, besides supplying a family from 7 to 9 persons, during the year, probably not short of 200 pounds. Another, from five cows expected to make 1,200 pounds.

In the Cultivator for September, 1845, we also find an article, entitled "*Connecticut Cheese Dairies*," which contains some interesting statistics on this subject. The average quantity of cheese reported from the single town of Goshen, is stated at 500,000 pounds; and of butter only about 40,000 pounds per annum. The average quantity per cow of cheese may

be estimated at 300 to 350 pounds. The first manufacture of the pine-apple cheese in America was commenced there in 1808, by Mr. Lewis N. Norton. A description is given of the mode of manufacture. He has 68 presses, and makes 28 cheeses per day; weighing, when dried, five pounds each, and it usually nets about 10 cents per pound. W. Norris Coe, of Winchester, (where one firm usually purchase about 500,000 pounds of cheese annually,) is also celebrated for making cheese, for which he usually obtains from 16 to 18 cents per pound, and which retails in New York and the southern cities at from 20 to 25 cents per pound. The two papers from which we have quoted above may be found in appendix No. 24.

Besides the dairy and its products, the *various methods of feeding cattle and stock* of different kinds, and *the use and value of their products*, may properly claim more than merely a passing notice. These are subjects which are extensively discussed in the ablest treatises, prize essays, and communications to periodicals, which continually issue from the agricultural press. The main difficulty is in making a selection, where there is so much that is valuable and well adapted to aid the agriculturist in every portion of our extensive country. It is a practice in many of the agricultural associations in England to invite, to aid in the discussion of subjects, men of distinguished science and practical knowledge; and thus much admirable instruction may often be found embodied in the reports of their meetings. The same, to a more limited extent, prevails in our own country. In the account of the meeting of the Loughborough Agricultural Association, contained in the Mark Lane Express of October 6, 1845, we find some valuable suggestions on the principles to be adopted in feeding cattle. They are the same as are adopted by the ablest lecturers on animal physiology on both sides of the Atlantic. Mr. Rawson, surgeon, after describing the elements in animals, proceeded to inform the meeting of the various uses of each. "Nitrogen," he said, "was the principal ingredient in flesh and muscles. Fat is composed of carbon and hydrogen. If they wished to make animal fat for sale or for show, they must feed it on carbonaceous food. Unripe straw is very carbonaceous. As the seed ripens, it becomes less so, and not so suitable for fattening. Cows generally feed well on aftermath. Half a pound of Swede turnips contains 110 grains of nutriment, while the same weight of white turnips contains only 85 grains. The outer temperature is very important; it should be brought as nearly as possible to the temperature of the blood. The same regard to temperature is necessary with respect to a milking cow. Fat is a mere deposite—a secretion; it does not impart strength—rather the contrary. Hence we do not make a horse fat for racing, but make him display muscular power. In fattening horses for sale, carbonaceous food, young grass, oil cake, Swede turnips, &c., should be given: in feeding for use, should be mixed with an equal quantity of other kind of food."

Liebig, it is well known, divides the elements into two distinct classes. Those which are formed by the combination of carbon, hydrogen, and oxygen, in different quantities, are what Liebig calls *elements of respiration.* Under this head are starch, fat, butter, sugar, and alcoholic fluids. By combining all the four elements, we obtain *the elements of nutrition*, or the *nitrogenized* constituents of food—such as vegetable and animal fibrine, caseine, albumen, and gluten. The constituents which are not nitrogenized are for sustaining the animal heat of the body, and protecting its parts; and thus provision is made to be used when the body is diseased. The

oxygen of the air destroys these. It is often found that if a cow is driven home from a considerable distance, instead of being milked in the field, much of the butter disappears, which is owing to the action of the oxygen of the air on those substances with which it most readily combines. The same reason, owing to the increased action of the muscles, is also why the milk of the cow after calving contains so little butter.

The less the food that is expended in maintaining the heat of the animal, the more butter she will yield. *Stall feeding*, it is thought, will effect this result; but then, as in the Dutch cheese, made where the cows are more confined, the product is not as well flavored. Most writers object to stall feeding on account of the want of exercise; and when the weather is warm there is no call for exertion to keep themselves warm, and the gentle motion they take increases the healthy state of the body, and thus they not only eat more, but also assimilate better their food. But in winter, the temperature being so much lower than their own bodies, and the air more condensed, and so containing more oxygen, they need more non-nitrogenized food to combine with the excess of oxygen; and hence it is that stall feeding, by preserving the warmth, produces a saving of food. The cooler the body is, the greater the expenditure of food.

On this account Mr. Bernays, the chemist, in his address before the meeting above mentioned, whose remarks we have thus embodied, recommends that the animals be regularly fed, have plenty of litter, and be kept clean. He says that if warmth is equivalent to food, the form in which food is given cannot be immaterial, and the more digestion is facilitated the greater the saving. By cutting up the food, some expenditure of force in its preparation is saved by the feeding animal. If the food contains water of a lower temperature than that of the animal, it must be raised to that temperature at the expense of a part of the food. Steaming obviates this difficulty. An ox, in a winter month, the air being 32°, consumed 60 pounds of mangel wurzel a day. No less than one twentieth of this food was needed in this case to raise the temperature of the water of the mangel wurzel to the temperature of the body of the ox. Pigs, likewise, thrive better on dry than on wet fodder.

"If the object be to increase and sustain the animal, as in the case of the young growing one," Mr. Wood also, a surgeon, says, "you choose those vegetables which contain a large proportion of muscular fibre or nitrogen and phosphate of lime for the bones; such as peas, beans, oats, barley, &c. If, in a full grown animal, you aim to sustain it and increase its fat, you give those vegetables which contain fat ready formed; as lentils, Indian corn, oil cake, &c. But with a mixed object in view, mixed food must be given, such as will produce bone, muscle, and fat, also." His explanation was—"There is no motion in an animal body, or emotion of mind, but what causes a corresponding absorption of the tissues of the body; and in order to keep up this daily waste, a certain amount of food is necessary. This is called sustaining the body. Thus, cattle working hard require a larger amount of food than when at rest. This necessity being attended to, constitutes health. But fattening is an unnatural condition, and requires an increase of substance. Hence the necessity of unnatural means, as the absence of exercise, light, and the influences of the atmosphere, a mixed diet, (to bring out all the materials of the animal body to the greatest perfection,) in a dry warm state. Mr. Childers's beautiful experiment proved that warmth alone, with an animal, would produce one third more of flesh,

and the expense of one quarter less food. Mr. Norton also proved that the absence of light, with warmth, produced still greater results. The reason of this is obvious. Every animal possesses both a nutritive and respiratory apparatus; the one to sustain the body, the other to support its vitality, by producing heat or warmth. This first object is effected by the gluten in the food principally, the basis of which is nitrogen; the second by the starch, sugar, and gum contained in the food, which form bile, the basis of which is carbon. The bile passes into the intestines, where it meets with oxygen, and thus becomes carbonic acid. In this state it enters the circulation, where it meets with peroxide of iron, (which the blood always contains;) the carbon unites with the iron, and forms carbonate of iron. In this state it passes to the lungs, where it meets with fresh oxygen during inspiration, which re-converts the carbon in the carbonic acid, which passes off during the expiration, while the peroxide of iron is re-formed and taken back by means of its carriers, to be again transformed into carbonate. The result of this combustion of carbon is heat. The heat of the animal body is nearly 100°. All food, therefore, before it can be assimilated, must be raised to its own temperature, which can only be done by the consumption of carbon; or, in other words, food. Potatoes, linseed cake, and oleaginous seeds, on account of the starch, sugar, oil, and gum they contain, are well adapted to accomplish this end." He then adverts to the great inattention which farmers pay to these principles, and adds: "Fat is a reservoir of carbon for the system to draw upon for the purposes of combustion, in the event of the food not containing a sufficient quantity of the proper elements to keep up the animal heat. As manure is the proper result attending the feeding of animals, it may be well to remark that its quantity depends upon the refuse of food and the amount of absorption going on in an animal's body; or, in other words, upon its own destruction; thus returning to inorganic nature, as food for vegetable life, the elements of its own nature. But the quality depends on the quantity of nutritious food given to the animal. The young growing animal, requiring increase as well as sustenance, consumes all the nitrogen and fatty matter in its food. The milking cow the same. But in the full grown feeding animal a large quantity of these ingredients is not consumed; a rich and valuable manure is the result."

Mr. Bernays also said that we must not judge of the value of the food by its *bulk*. Green top turnips, mangel wurzel, and red beet contain 89 per cent. of water, Swedes 85 per cent., potatoes 72 per cent., oats and wheat straw 18 per cent., hay, peas, and lentils 16 per cent., and beans only 14 per cent. He likewise stated that we should distinguish between fleshening, or the formation of muscle, and fattening, or the formation of fat. "According to the supposed fattening properties of food, it ranks thus: 1st, oats, barley meal, and hay; 2d, beans and peas; 3d, lentils, potatoes; 4th, turnips and red beet. According to their fleshening properties, they stand thus: 1st, lentils; 2d, beans; 3d, peas; 4th, flesh; 5th, barley meal; 6th, oats; 7th, hay; 8th, carrots and potatoes; 9th, red beet; 10th, turnips. 100 pounds of lentils are supposed to be capable of yielding 33 times as much muscle as 100 pounds of turnips." On this account there is great advantage in mixing food. "An animal fed chiefly on oil cake would, on being turned out, increase in size much more slowly than the animal which has been fed on hay, or on turnips and hay. The oil cake produces chiefly fat and little flesh; hence the movement of the animal will consume much of the ready formed fat or tallow. It is only where the oil cake is given with flesh-

ening food, such as beans, oats, and hay, that lean is proportionably formed. Warmth, confinement, and fattening food, are most favorable for the formation of butter, fat, and tallow. Herbage, which is generally denominated *poor*, but which, in reality, is *rich* in nitrogenized constituents, and which cows have to crop themselves, is favorable to the formation of cheese, but not of butter." He recommended food also to be given to animals in a warm state, "a little lower than the temperature of their own bodies." We have given somewhat at length the above account, as the science of nutrition seems to be presented in a very clear light, and the results of practice, in a great degree, will be found to correspond with the theory.

Some very interesting facts are stated on these subjects in a prize essay on fat and muscle, by W. F. Karkeek, veterinary surgeon, Truro, and which is published in the Quarterly Journal of the Royal Agricultural Society, vol. 5. After stating the theory of nutrition, he says: "From what has been stated, then, we may very safely conclude that fat is chiefly produced from the starchy matters contained in the food of animals, all the excess of which that is not consumed in producing animal heat is taken back into circulation, and deposited in the form of fat, in cells appropriated for that purpose. It would appear, also, that the bloodvessels have the power of taking back the fatty matter again into the circulation when it is required, so that one of the objects which this disposition fulfils is to store up, when nourishment is abundant, a supply which may be taken back into the system and made use of in time of need." He then adverts to Professor Playfair's discovery, that "animals possessing small lungs, small livers, and small spleens, indeed small offal of every description, have a greater disposition to fatten, and to lay that fat on the proper places," or a fair proportion of fat and lean, "than coarse-bred, ill-proportioned animals, which will be found to possess larger offal than well bred animals, in proportion to their size and growth;" and also mentions another fact, which has likewise been ascertained in consequence of inquires respecting the former statement, "*that in proportion as an animal fattened, so in proportion did the organs which are chiefly connected with nutrition become diminished in size*—a fact which he says is intimately connected *with the breeding, rearing, and feeding of animals*."

He illustrates the above position by reference to facts, and then draws the conclusion "that by pursuing the system of breeding from fatted animals, or from those having a great tendency to fatten, *function* must re-act on *organization*, and at last those qualities become not not only increased, but fixed in the race. He refers to different breeds to prove this.

He next adverts to certain *external signs* or *tokens* which indicate early maturity, or a determination of the animal frame to produce fat or muscle in an eminent degree—as, first, *touch:* as a thick, hard, unyielding hide indicates a bad feeder, while a thin, papery-feeling hide, covered with thin hair, indicates the reverse, as such an animal will speedily fatten, but not carry mnch muscle; and this, too, indicates a delicate constitution. "The perfect touch," he says, "in a feeding animal, will be found with a thick loose skin, floating, as it were, on a layer of soft fat, yielding to the least pressure, and springing back to the touch of the finger like a piece of chamois leather. This indicates hardiness of constitution, and capability of carrying plenty of muscle, as well as sufficiency of fat."

Smallness of bone is also another indication. "The *size of the head:* when the head of the bull approaches to the narrow elongated form of the

female, his stock will be certain to fatten readily, but will not carry much muscle;" *thin ears, fine horns, proportionate union of length, depth, thickness, &c.*

Another fact to which he alludes as important is, that "nearly the whole of the fleshy part of an animal which will afford any profit" to the farmer, "is assimilated chiefly during the period of its growth." "Thus the object of the farmer, whose purpose is profit, will be to force his stock on, during the period of their growth, by such kind of food as will produce the largest quantity of muscle at the least expense."

He recommends that growing stock, therefore, be fed with peas, beans, and barley meal, in conjunction with good hay, grass, and turnips, varied according to seasons and circumstances; also a change of diet, which he asserts is proved to promote health and appetite more than by limiting the quantity and quality. He gives, to aid in this, the following table, constructed by him from Johnston and Boussingault, in which the gluten, &c., indicate the *fleshening* properties, and the starch, gum, and sugar, the *fattening*.

	Produce per acre.	Weight of grain per bushel.	Weight of gluten, albumen, and caseine.	Weight of starch, gum, sugar, and fat.	Weight of water per acre.
One acre of—			*Pounds.*	*Pounds.*	*Pounds.*
Field beans - -	25 bush.	64 lbs.	450	672	256
Peas - - -	25 "	66 "	380	845	208
Oats - - -	50 "	42 "	290	1,168	336
Hay - - -	3 tons	–	480	2,790	752
Potatoes - -	12 "	–	600	3,330	20,250
Carrots - -	25 "	–	1,120	5,800	47,600
Turnips - -	30 "	–	800	6,700	56,950
Wheat straw - -	3000 lbs.	–	40	940	450
Oat straw - -	2700 "	–	36	970	324
Barley straw - -	2100 "	–	28	646	252

In commenting on this result, he says that "Swede turnips well may be called the raw material for the manufacture of beef." He points, also, to "the peculiar adaptation of the carrot crop to the rearing and fattening of stock," and also to the quantity of water contained in these roots, as rendering it desirable that dry provender, such as oat or barley meal, oat-straw, hay, or pea-haulm, be given to sheep to prevent the frequent scouring of these animals, and which, by making the food remain longer in their stomach, will impart a greater quantity of nourishment. "The best kind of food for pigs," he says, "is a mixture of barley meal, peas, and potatoes." Potatoes are frequently used by themselves for this purpose; but neither the fat nor muscle of pigs fed in this manner can be compared with corn grain and peas-fed pork, the fat having a tallowy appearance, and both fat

and muscle shrinking for want of firmness when boiled." Mr. Karkeek's whole essay may be read with profit by the agriculturist.

The editor of the Cultivator is disposed to doubt some of Mr. Karkeek's conclusions, especially that animals having naturally small lungs are most disposed to fatten is sustained by practical observation; and if it were demonstrated, he thinks it would by no means follow that farmers should breed cattle with this organization. He refers also to the West Highland cattle of Scotland to show that a tendency to fatten is not inconsistent with strength of constitution and muscular vigor. He, however, admits the great excellence and utility of Mr. Karkeek's essay.

In one of the numbers of the Cultivator, we find the following rules, which we subjoin, as furnishing the editor's ideas on the subject of fattening animals: "There are some rules which may be advantageously adopted in feeding animals, which, however obvious they may be, are too often passed over or neglected. Some of these will be specified; and,

"1st. *The preparation of food.*—This should be so prepared that its nutritive properties may all be made available to the use of the animal; and not only so, but appropriated with the least possible expenditure of muscular exertion and energy. The ox that is obliged to wander over an acre to get the food he should find on 2 or 3 square rods; the horse that is 2 or 3 hours eating the coarse food he would swallow in 15 minutes if the grain was ground or the hay cut, as it should be; the sheep that spends hours making its way into a turnip, when, if it were sliced, it could be eaten in as many minutes; the pig that eats raw potatoes or whole corn, when either cooked could be eaten in one-fourth the time—may indeed fatten, but much less rapidly than if their food was given them in a proper manner. All food should be given to a fattening animal in such a state that as little time and labor as possible on the part of the animal shall be required in eating.

"2d. *The food should be in abundance.*—From the time the fattening process commences until the animal is slaughtered, he should never be without food. Health and appetite are best promoted by change of food rather than by limiting the quantity. The animal that is stuffed and starved alternately may have streaked meat, but it will be made too slowly for the profit of the owner.

"3d. *The food should be given regularly.*—This is one of the most essential points in feeding animals. If given irregularly, the animal indeed consumes his food, but he soon acquires a restless disposition, is disturbed at every appearance of his feeder, and is never in that quiet state so necessary to the taking on of fat. It is surprising how readily any animal acquires habits of regularity in feeding, and how soon the influence of this is felt in the improvement of his constitution. When at the regular hour the pig has had his pudding, or the sheep its turnips, they compose themselves to rest with the consciousness that their digestion is not to be unseasonably disturbed, or their quiet broken by unwonted invitation to eat. All creatures fatten much faster in the dark than in the light, a fact only to be accounted for by their greater quiet. Some of those creatures that ar, & s most irritable and impatient of restraint while feeding, such as turkeys and geese, are found to take on fat rapidly when confined in dark rooms, and fed at stated hours by hand. There is no surer proof that a pig is doing well than to see him eat his meal quickly, and then retire to his bed to sleep, or cogitate until the hour of feeding returns."—*Albany Cultivator.*

The fact that sugar is contained in food has suggested the idea of using it as a means of feeding cattle. Molasses has accordingly been tried, and it is said with good results. Another case of the application of saccharine food is thus given:

"*Saccharine food.*—The Manchester Guardian, after quoting a paragraph from our last week's paper on the use of molasses for feeding cattle, says: 'Some 30 or 40 years ago, Dr. Cartwright, the inventor of the power-loom, communicated to the board of agriculture an interesting account of some experiments he had made on the effects of sugar in fattening sheep. He states that he gave to fifteen sheep 4 ounces of sugar per day each, mixed with other food, and in the short space of 28 days found that, on the average, they had increased one fifth in weight, and that two of them had increased upwards of one fourth. As to the cost of the sugar, he was of opinion that sugar, supposing it to be purchased at 4*d.* per pound, would, at the rate of 4 ounces per day, be paid for in a return of flesh, exclusive of the advantage of expeditious feeding and the benefit to be derived from the manure.'"—*London Times.*

The loss sustained by driving cattle, instead of transporting them on steamboats and railways, has been tested in Great Britain by experiment; and we find it stated in the Mark Lane Express, that "Mr. D. Martin, of Wainfleet, sent five sheep to London, to walk the whole distance on the road, and killed five others at home. The two lots were of exactly equal weight (858 lbs.) when alive. The carcasses were weighed when dead, when it was found that the sheep which had walked to London weighed 435 lbs., and their loose fat 60 lbs.; while the five killed at home reached 489 lbs., their loose fat weighing 74½ lbs. The total difference amounted to 68½ lbs., or 14 per cent. of the original weight of mutton; and this was evidently the loss of meat occasioned by compelling the five sheep to walk from Lincolnshire to London."

We take the following from an agricultural journal, the Maine Cultivator. It may, perhaps, admit of some doubt how far the quality of the milk might be affected by such a process of fermentation as is described. It would seem to resemble too much that obtained by feeding on distiller's slops, which have been the subject of so great complaint in New York city and elsewhere. "M. Chabert, the director of the veterinary school at Alford, England, had a number of cows which yielded 12 gallons of milk each per day. In his publication on the subject, he observes that cows fed in the winter on dry substances give less milk than those which are kept on a green diet, and also that their milk loses much of its quality. He published the following recipe, by the use of which his cows afforded him an equal quantity and quality of milk during the winter as during the summer: Take a bushel of potatoes, break them whilst raw, place them in a barrel standing up, putting in successively a layer of bran and a small quantity of yeast in the middle of the mass, which is to be left thus to ferment during a whole week; and when the vinous taste has pervaded the whole mixture, it is then given to the cows, who eat it greedily."—*Maine Cultivator.*

In [illegible] with the true principles of feeding cattle, is that of *soiling*, of which the editor of the American Agriculturist remarks: "The true principle of soiling consists in the combination of both pasture and stall or rack feeding; and where circumstances will justify it, both should be united at the same time. An abundance of succulent grasses, clover, pea-vines, cornstalks, or vegetables in the yard, with a supply of salt, lime,

ashes, and sulphur, with a daily ramble in the pasture for a few hours, where easily accessible, or, if not, then as often as practicable, would undoubtedly most effectually secure the greatest quantity of milk."

This subject has also been discussed in the New York Farmers' Club, and we may refer to the report of that meeting in the number of the New York Farmer and Mechanic for May, 1845, to present here some of the views there expressed. The advantages of soiling are thus stated by Johnson, in his Cyclopœdia: 1. Saving of land; 2. Of fencing; 3. Economy of food; 4. Better condition and greater comfort of cattle; 5. The greater product of milk; 6. The manure obtained.

Mr. Pell, of Pelham, New York, says that eight acres will afford more and better food than forty would, pastured; and the manure saved is sufficient to pay the interest of a large farm. "The Hon. Josiah Quincy, of Massachusetts, says, 'at the end of the soiling season I had $200 worth of manure; had kept 20 head of cattle on 17 acres; by pasturing, I had to allow 50 acres for 15 head; had my stock in prime condition; a full supply of milk all the season; saved all expense in cross-fences, (not requiring one rod of interior fence on my whole farm,) while previously I had 1,600 rods of fencing, and paid $60 yearly for repairs. The additional expense I had gone to in curing the food, and giving it to the animals, amounted to $163. My manure alone paid for this, and no consideration would induce me to abandon it.'" Others also gave their opinion in its favor. Dr. Underhill said, that where land was worth $50 to $150 per acre, he had no doubt of the value of soiling cattle. The manure pays for the expense of thus feeding, and less land is needed. He recommends combining with it the root crops. He mentions, also, in its favor, that in summer cattle suffer far less from flies and heat, cows give more milk, fatten more easily, and require less food; more manure also can be made in this way; and by adding leaves, &c., these resources are greatly increased; while he thinks the stock fattens with one-fourth less food.

Mr. Townsend also gave his opinion in favor of it. He soiled seven cows and a pair of horses on the produce of five acres. If they had been fed out, the feed would have been small for them. A number of papers on feeding and fattening cattle, &c., will be found in appendix No. 25.

The number of cattle in our country is great, and it is in many parts increasing rapidly. In the single county of Chester, Pennsylvania, a writer in an agricultural journal says that there are annually fattened 50,000 head. He states that in Lancaster and other adjoining counties there is also a growing enterprise in raising cattle and preparing them for market, owing to the fact that by the cessation of many distilleries, the grain which was so consumed is now converted into food for stock. The Chicago Democrat, speaking of that place, says: "We are inclined to the belief that Chicago is destined to be the greatest beef market in the United States, if not in the world. Beef fed on the prairies is always the tenderest and sweetest, which gives us the preference in the outset. Beef is now being packed here not only for the New York and Boston markets, but also for the Montreal and London markets. Messrs. Wadsworth, Dyer, & Chapin have been, and still are, slaughtering one hundred head of cattle daily, and they have now already engaged five thousand head to be slaughtered immediately. They are now packing both for the United States navy and the British government. Other firms are packing, but not so extensively as Messrs. Wadsworth, Dyer, & Chapin. We think something like two

hundred to two hundred and fifty are slaughtered in our city daily, and this number will soon be increased. The average price now paid by our packers is $2 50."

The subject of *sheep* has occupied much attention from various writers in the agricultural papers during the past year, and it is evident that there is an increasing spirit of enterprise, with regard to this species of stock, in different parts of our country. Considerable discussion has taken place as to the different breeds and the purity of the stock of Merinoes, as large flocks are mentioned as purchased in Ohio for States further west. Sheep are raised for a double object: for their wool, and for their flesh as food, and also for the sake of their tallow.

In an article in one of the agricultural journals, referring to an account of the trying up of sheep in one of the British colonies, the writer makes the following observations: "Whenever wool reaches a certain minimum price, the pelt, carcass, and tallow are worth more for the shambles than the animal is for his fleece; and it may be worth the inquiry, whether, on sufficiently cheap and well adapted pastures, sheep may not be a very profitable production for this object alone. It is certain that our western farmers have, for some years, found their advantage in slaughtering many thousands annually for this purpose. It would, perhaps, not be an extravagant estimate to put the number thus slaughtered in New York and Ohio alone at over 100,000 during the past season; and that, too, while wool is comparatively high, and with every prospect of continuing so. 30,000 have been thus disposed of in Buffalo and Cleveland—a single point in each of the above States. The business has been reduced to a perfect system in the colonies above named. Mr. Lloyd, of a steam-melting establishment at Port Philip, says: "We have given the result of tallow, that may be depended on, (our most anxious study,) and have arrived at the following conclusions, which we are certain will be found correct: 1st. That a sheep of the ordinary Merino breed, weighing 55 pounds, is just in nice condition for the shambles, and will produce, at the melting establishment, 20 pounds tallow; and for every pound over 55, four-fifths will be tallow. 2d. Young sheep, say two-toothed, will not produce as much as four-toothed and upwards, of same weight. The following results were obtained from six flocks of different average weight:

"Those averaging	44	pounds produced	$15\frac{1}{2}$	pounds tallow each.
	47		$16\frac{3}{4}$	
	48		$17\frac{1}{4}$	
	52		19	
	54		$19\frac{1}{4}$	
	65		$27\frac{1}{2}$	

"The above tallow was worth 28 shillings per cwt., which brought the average value of the lowest flock to 3*s.* 2*d.*, or 75 cents each; while the best reached the very handsome price of 6*s.* 10*d.*, or about $1 60 each, besides the pelt, which is usually worth 35 to 60 cents in addition. In this country the hams are extracted and cured like dried beef, or venison, and find a ready sale." We find various estimates of the quantity of wool cropped in different sections of the country. Thus, the Cincinnati Chronicle thinks the wool produced in Ohio amounts to about 2,000,000 pounds per annum. In Jackson county, Michigan, the yield is estimated at 50,000 pounds—worth $12,000.

In Ohio: "In the county of Richland, 200,000 pounds of wool have been

sold during the past season, at an average price of 30 cents per pound."

"*Wisconsin wool.*—There will be shipped from Wisconsin this season 50,000 pounds of wool, the clipping from 25,000 or 30,000 sheep in the Territory. A great portion of this large quantity will be sent to market from Racine, a flourishing village on Lake Michigan."

The Chicago account of the market, under date of June 23, says the whole receipts of wool there for the season would amount to 50,000 pounds. In the early part of the season, quoted by another public journal, we have the following statistics, which it may be useful to transcribe: The basis of the calculation is the year 1836, at which time there was in the country 12,897,658 sheep, each fleece averaging $3\frac{1}{4}$ pounds—making 41,917,324 pounds; excess of imports over exports for same year, 12,286,249: making total amount of wool in the country 54,214,573 lbs. Consumption estimated same year, 51,000,000 pounds. Excess of foreign and domestic wool over probable consumption, 3,213,573 pounds. In consequence of the inaccuracy of all such calculations, a reasonable allowance should be made; but, taking the above as the correct data, it is found that about one-fourth of the whole amount of wool in the country at that time was foreign, the estimated value of which was $1,270,000. Since then importations have fallen off gradually, with the exception of one or two years, while in domestic a great increase has taken place. The opinion of the increase of sheep varies from 15 to 33 per cent. per annum; but taking the minimum (say 15 per cent.) on 12,897,658, in 1836, up to the last year would give 33,000,000 sheep, which would yield at the rate as above 107,250,000 lbs. of wool. This year we have at the same rate over 38,000,000 sheep, and 123,500,000 lbs. wool; being an increase of 16,000,000 lbs. over last year, which, even at the low price of 25 cts. per lb., would on the whole clip amount to $30,875,000. When this statement was made, there was not taken into account Illinois, Indiana, Michigan, and Iowa, which at present have a great number of sheep. They increased rapidly last year, as the high price of wool induced a speculation in sheep; and the spring being favorable for lambs, the increase was unusually large in the old wool-growing States, part of which was driven into the new States, instead of coming east to be slaughtered as usual. The cheap and fertile lands and climate of these States make them well adapted for raising the lower grades of wool, and 18 to 25 cents in the eastern cities would remunerate them well, as the cost of transportation is very trifling upon their value, in comparison with other articles raised in the west. At these prices the foreign wool, which is now used for blankets, jeans, &c., would be driven entirely from the market. This would not be all; but we would have England and France as constant purchasers, as they would prefer our wool at these prices over the Mediterranean and Buenos Ayres wool, of which at present they are large consumers. The subject is well worthy of the western wool growers' attention. The time is near at hand when they will have to grow wool cheap enough for export, as we will have more than we can consume. Imports of wool:

	1844.	1843, 9 mos.	1842.
Cost under 7 cents	10,157,839 lbs.	2,866,211 lbs.	8,427,099 lbs.
Cost over 7 cents	130,161 "	217,285 "	739,240 "
Total -	10,288,000	3,083,496	9,166,339

This period includes from October 1, 1841 to January 30, 1844; and the table shows a yearly import of 7,835,255 lbs., or nearly 3,000,000 lbs. under the import of 1844.

The English papers state that in the months of August and September about 500 bales of wool were received from the United States; and during a subsequent month it is stated that 1,500 bales had been shipped to England from New York and some other ports. The importation of wool into Great Britain and Ireland, for 1844, was as follows: "*Importation of wool into Great Britain and Ireland in* 1844.—By an official report of the House of Commons, we find that the total quantities of sheep and lamb's wool, foreign and colonial, imported into the United Kingdom during the year 1844, amounted to 65,079,524 lbs., of which 5,402,098 came from Russia; 1,609,099 from Denmark; 21,847,684 from Germany; 1,346,613 from Portugal; 2,818,353 from Italy; 1,286,963 from Turkey, Syria, and Egypt; 1,101,284 from Morocco; 2,197,031 from Cape of Good Hope; 2,765,853 from East Indies; 2,186,291 from the States of the Rio de la Plata; 12,406,397 from New South Wales; and 4,411,804 from Van Dieman's Land. The total quantities re-exported from the United Kingdom amounted to 1,924,826 lbs. Exportation of wool from the above countries during the same year amounted to 8,947,619 lbs. Importation of other wools:—The quantities of wool of the alpaca and lama tribe imported during the year 1844 amounted to 635,357 lbs., of which 47,848 lbs. were re-exported to Belgium and France. The quantity of mohair or goat's wool so imported during the same period amounted to 1,290,771 lbs., of which 97,529 lbs. were re-exported."

"*Exportation of woolen manufactures.*—The gross total declared value of the British woolen manufactured cloths, &c., exported from the United Kingdom last year amounted to £8,204,836. Yarns of woolen and worsted, including yarn of wool or worsted mixed with other materials, 1,271,906 lbs."

In connexion with the subject of raising sheep, &c., we would refer to the appendix No. 26, where will be found some interesting papers. Among these is one on sheep husbandry of Kentucky, by Judge Beatty.

That the south affords great facilities for raising sheep has been repeatedly stated. In proof of the productiveness of this kind of stock in South Carolina, we find it mentioned that "Leicester lambs, 14 months old, from the flock of Colonel Wade Hampton, sheared from 11½ to 13¼ pounds of wool; and that 60 head of lambs dropped the *present year*, and shorn when hot weather came on, to relieve them from the oppressive heat of summer, averaged four pounds each." In the appendix No. 26, above mentioned, will also be found a very interesting letter from Germany, written to this office by Charles L. Fleischmann, esq., (formerly draughtsman in the Patent Office) respecting the fine-wooled fleeces of Prussia. Mr. Fleischmann having been thoroughly educated both as a scientific and practical agriculturist, in the celebrated Agricultural Institution of Schliessheim, in Bavaria, is well qualified to furnish valuable information on all the topics connected with agriculture; and the large collection of samples of wool which he expects to bring over to this country, will no doubt be of great value to those who are desirous of having the opportunity to select fine animals. He purposes also, it is believed, to lecture on this and kindred subjects connected with agricultural improvements on his return to this city. It would seem, from his letter, that the far-famed and long-celebrated Merinoes and Saxonys have lost their repute, and that the Prussian

sheep now hold the first rank; or, as he expresses it, have the "constant character." Mr. Fleischmann will be able also to give much information as to the mode of keeping sheep, &c.

Mr. Bingham, of Cornwall, Vt., gives, in one of the agricultural papers, the following account of his management of sheep: "My mode of management is this: I assort according to age and condition—the oldest by themselves; middle-aged, young ones, &c., into about nine different flocks, summer and winter. My hay is a mixture of timothy and white and red clover. I feed from 12 to 14 tons to 100 sheep, which is the principal feed, except for my stock-bucks, oldest ewes, and weakest lambs, to which I feed a small quantity of roots, with mixture of corn-cob meal. I feed my sheep in the pure air, in racks, and have sheds to shelter them in case of storms. My ewes and rams commence breeding at two and three years of age. The general average of lambs I raise is 97 to 100 ewes. Last year I raised from 132 ewes the same number of lambs. There were no twin lambs. I put my buck with the ewes about the first of December. I put the buck with the ewes about two hours each day, marking him on the brisket with red chalk; and then what ewes I find marked red I remove before putting in the buck again. At the time of lambing they run in the pasture, taking care to have them sheltered in case of storm. The live-weight of my bucks over one year old is from 115 to 145 pounds; the live-weight of ewes from 85 to 130 pounds. Buck lambs, four and four and a half month sold, weigh from 50 to 70 pounds. I sheared last year 530 fleeces; the average weight per fleece was 4 pounds 14 ounces. The sheep were washed in a stream of clear running water. I commenced shearing four days after washing. There were 51 yearling bucks, and 37 over one year old. The remainder of the flock consisted of stock ewes, one and two years old, and a few wethers. The average price of my wool last year was 46 cents per pound, with the exception of 334 pounds of grade wool. There has been no disease among my sheep excepting the grub in the head, which occasions more deaths, in my opinion, among sheep, than any other disease. The following I consider a sure remedy: To 100 sheep one and a quarter pounds Scotch snuff, mixed with four quarts of water. Throw it up each nostril by means of a syringe. This operation is performed by cutting a hole through a board large enough to admit the nose of the sheep two-thirds of its length from the eyes. It keeps the head perfectly steady, so that there is no difficulty in performing the operation. The average weight of my wool per fleece, this year, is five pounds three ounces. It is still unsold. I sheared this year 587 fleeces.

"MERRILL BINGHAM.

"Cornwall, Vt., *September* 8, 1845."

The following relates to wool-growing on the prairies of Illinois; it is communicated to the Albany Cultivator, by Messrs. T. & I. Harvey, of La Salle, Illinois: "But a few years since we emigrated from Vermont to this State. We soon became satisfied that wool could be grown much cheaper here than in our own native State. In 1843 we purchased in Columbiana county, Ohio, 2,300, and drove them through by land into this region. In crossing streams, without bridges, we managed to take about 50 to the water's edge at a time; and, by the aid of two shepherd's dogs, would crowd them into the river. Then these two dogs would go and aid the one that was left to guard the main flock, and urge them all up and

into the stream together. They would all swim over without much difficulty. They travelled generally about 12 miles a day. On our arrival home we let and sold all but 1,200. Our rule for letting was for one half the wool, and one half the lambs, and as many sheep returned as let, at the end of the year. We wintered them on prairie hay, and a very little grain fed after the month of February, not to exceed 160 bushels of corn. The first winter we lost about 60, and raised over 400 lambs. The second winter we fed part of the flock on timothy and clover—the balance on wild prairie hay. Those fed on the prairie hay did equally well as those fed on the English grasses. We met with considerable losses by dogs the second winter; otherwise the sheep came through finely without grain, except to about 30 stock bucks wintered by themselves: these we fed with a little grain daily through the winter. Our flock, at this time, amounted to about 1,050. We also raised this season over 400 lambs. The first year our flock yielded a little short of three pounds of wool to each sheep, and sold for 33 cts. This season we sold for 27½ cts. per lb., and the yield increased a little over one-quarter of a pound to the fleece. We procured good rams, in Ohio, at $10 each—said to be full-blood Merinoes. It is no more than justice to acknowledge the increase of our second clip from a lot of 64 lambs got by a yearling buck which we ordered from Vermont, from the flock of S. W. Jewett, said to be a son of his stock-buck Fortune. Every fleece from this flock of 64 was weighed as soon as shorn, and we did not find one that sheared less than 4 lbs. The lot averaged over 5½ lbs. One lamb, got by this young buck, and out of a ewe we purchased of Mr. Jewett, which dropped in the month of April, sheared this season a fleece of 8 lbs. 15 oz. of beautiful wool. We therefore have become satisfied of the difference in the breeds of sheep. We might have added that these two Vermont sheep bore the first prize at our State and county shows in 1843 and 1844. We think our sheep are better washed than we used to clean them in Vermont. Our mode of washing is cheap and expeditious. We run two fences angling from the stream where we wash, to guide the sheep at the terminus. We build a platform over the river; then, by the aid of our dogs, run them over this platform as fast as possible to give motion to the water. They are obliged to swim about four rods to strike the opposite bank. Then return them across a shallow place below, where they can wade the stream. We jump them off this plank work into the river three or four times, till we are satisfied that they are thoroughly cleansed. In this manner we might with two men and two dogs wash 10,000, if at hand, in one day. We cut wild prairie hay from land owned by government, and speculators who do not occupy. On contract, it is delivered in our yards at $1 each ton. The yearly cost of keeping our sheep cannot be over 30 cts. per head. One boy we employ the year at $8 per month. He has the sole charge of the flock, with the aid of two shepherd's dogs, which we could not do without. They aid in yarding them nights, and keep off the small prairie wolf. A Scotchman by the name of Mitchel raises and trains these shepherd dogs, from a pair of Scotch collies, imported by Murray & Co. He sells his puppies at about $4 each. Yours, &c.,

"TRUMAN & ISAAC HARVEY.

"La Salle, Ill., *September* 25, 1845."

The following table exhibits the results of the experiments of the distinguished agriculturist De Raumer on the effects produced by an equal

quantity of several substances in increasing the flesh, tallow, and wool of sheep.

		Increased the weight of the living animal.	Produced wool.	Produced tallow.
1,000 pounds	potatoes raw, with salt	46½ lbs.	6½ lbs.	12½ lbs.
Do	potatoes raw, without salt	44	6½	11½
Do	mangel wurzel, raw	38½	5¼	6½
Do	wheat - -	155	13	59½
Do	oats - -	146	10	42½
Do	barley - -	139	11½	60
Do	peas - -	134	14½	41
Do	rye, with salt -	133	14	35
Do	rye, without salt -	90	22½	43
Do	meal, wet - -	129	13⅓	17½
Do	buckwheat -	120	10	33

These results are said to agree with those of De Bombasle, and with those of a number of other agriculturists.

Connected with the subject of sheep may be noticed also the efforts that are making to introduce the *alpaca* into this country. Governor Paine, of Vermont, it is stated, has sent for a pair of these animals, to make trial of them; and we see it mentioned, likewise, that an association is formed in New York city which intends to appropriate some $4,000 or $5,000 to the same object. The Nashville Agriculturist, too, has the following notice:

"A company has been formed among the most wealthy and influential farmers of Bourbon county to import several alpacas immediately into this State. The shares are all taken, and the money paid in. A man has been chosen, and an agreement made with him to start before Christmas to South America for them; so that, within the next year, you may count with certainty upon seeing this most interesting and important experiment tested in Kentucky, by Kentucky farmers, to an extent and in a manner that must insure success, if our climate is at all suited to the constitution of this most valuable animal. Before I write to you again, I hope to see some of the company, and to be able, in my next, to give you a more detailed and particular account of this important movement."—*Nashville Agriculturist.*

The following fact shows the importance of this movement to introduce the alpaca into our country, both at the north and south; and we cannot doubt that our climate will be well adapted to them, and that they may also prove to us a source of national wealth. The cloth manufactured from their wool is now well known in the list of our cloths. At a late meeting of the British Association for the Advancement of Science, Mr. W. Dawson stated that six years before, he brought before that society a subject that received its countenance in an especial manner; which was, to induce manufacturers to exercise their ingenuity to discover means for consuming a wool of a silken texture in a manufactured state, and also to prepare the landed gentry and farmers to naturalize the animal called the alpaca, a species of sheep that eat that which the cow, the horse, the common sheep, &c., reject. He added: " The manufacturers have succeeded beyond my most sanguine expectation, and the naturalization also. The former has created a national wealth of £3,000,000 to £5,000,000 per annum; the latter is progressing rapidly. I have proved that these mountain rangers can be domiciled in our own country, though brought from beyond the

Andes mountains in Peru. I have tried the experiment in my own lands on the west coast of Ireland, in the wildest districts of the county of Kerry, and already a company is on the tapis to bring over 10,000 of those animals for the national good." He said that the race was nearly extinct in Peru, and therefore it was desirable to bring it over to the British isles; their wool approaching silk, and their flesh being improved by English air and pasture. The Queen and Prince Albert were wearing royal robes from the wool of some bred in Windsor Park. And he gave it as his opinion that "*in ten years these animals will add* £20,000,000 *per annum to the national wealth.*"

The Mark Lane Express has the following notice of the attempts to domesticate the alpaca in Great Britain; which seems to afford strong hope that the animal, when introduced here, will succeed:

"*The alpaca.*—It may be satisfactory to persons interested in the naturalization of this useful animal in the British isles to learn that some of the latest experiments have been singularly successful, fully establishing the fact that upon our soil the fleece improves in quality and in weight. G. A. Stirling, esq., of Craigbarnet Place, (Lennoxtown,) near Glasgow, lately sent 15 lbs. to Yorkshire, the residue of two fleeces clipped last year, the quality of which, although not finer than the best sorts imported, was nevertheless more glossy, and of one uniform jet color. This small parcel was since spun by Mr. James Whitley, of Morton mills, and manufactured by Gregory Brothers, of Shelf, into a web of thirty yards, mixed with ruby silk, the figure rose, shamrock, and thistle, (Queen's pattern,) on alternate stripes of black and ruby. This is the second instance of home-grown Alpaca being manufactured in this country, the first having been the Queen's, in last December. About two months ago, Sir Robert Heron, M. P., of Stubton, near Grantham, Lincolnshire, sent down a black fleece, just shorn on his own estate, with the view of ascertaining its mercantile value, which, by professional men, was pronounced the most splendid they had ever seen. It weighed 17 lbs., a most extraordinary weight; the fleece in Peru seldom, or ever, exceeding 10 lbs. This remarkable specimen of home-grown was sold to Messrs. Gregory Brothers at 2*s.* per lb. At the same time Sir Robert forwarded to the manufacturers a *machurga* fleece, white, and weighing 8 lbs., clipped from the hybrid, obtained by crossing the lama with the alpaca. This animal was imported from Peru, and purchased at Liverpool in the winter of 1842, and may justly be considered a curiosity, as being a rare specimen among us. In Peru this mixture is frequent; but, like the mule, the offspring is barren, and never used unless as a beast of burden. The fleece in question possesses some of the properties of the alpaca, such as its length, and a partial glossiness, mixed with the harsh hair and kemp of the lama, which, of course, is not a wool-bearing animal. The difference between this and the alpaca fleece is so great, that it is difficult to say what mercantile value can be set upon it. Samples of the three fleeces, above mentioned, together with patterns of the Queen's textures, including her favorite plaid, have been deposited at the Polytechnic."

Hogs, also, form an important item in the agricultural productions of our country; as the raising of swine is closely connected, in many parts of the land, with farming operations. A variety of articles relating to this subject may be found in appendix No. 27. A writer in the Cincinnati Chronicle says, that, taking the census of 1839 as the basis of calculation, there were 26,301,293 hogs in the United States, which, at 180 lbs. average for each,

and allowing them to be worth $3 50 per cwt., their value would be not less than $160,000,000, or three times the entire cotton crop for the year 1845. He supposes that, in the western States, commerce consumes about one-sixth of the whole number, though a less proportion probably would apply to the whole United States. He then enters into several comparisons, and, taking McGregor's statistics as his authority, says that the number of swine in all Europe, calculating on an increase of 10 per cent. on the table he gives for 1828, were as follows:

Russia	16,380,000
Austria	6,050,000
Great Britain	5,775,000
France	4,950,000
Italian States	2,750,000
Bavaria	1,650,000
Netherlands	1,540,000
Prussia	1,645,000
Sweden	1,320,000
Spain	1,100,000
Portugal	770,000
All other States	2,348,000
Total	46,278,000

Thus it seems that Russia, Austria, and Great Britain, with a population of 120,000,000 of people, have only as many swine as the United States with only 20,000,000. Eight western States, with a population of only 6,000,000, have as many as Great Britain, France, and Prussia, with 75,000,000. The proportion of swine in the United States is to Prussia as 6 to 1; Austria, 9 to 1; Great Britain, 7 to 1; France, 10 to 1; Spain, 16 to 1.

It is said in one of the public journals, that "A gentleman in the trade, just from Cincinnati, says the number of hogs slaughtered there in November will be at least 70,000. There is a strong body of eastern men on the ground buying. It was estimated that Kentucky would turn out 90,000, against 45,000 last year. Many hogs were being driven from the south in consequence of the scarcity of corn." An article in the American Agriculturist, quoted in the Ohio Cultivator, earnestly advocates the advantages of feeding and fattening hogs of a younger age than is commonly practised. He makes his calculations as follows:

"The pigs used for experiment were of three litters, from my own piggery, viz:

"A, three pigs, half Chinese and half Berkshire.

"B, three pigs, half grass and half Berkshire.

"C, three pigs, of same family as B, but a subsequent litter.

Class.	Farrowed.	Slaughtered.	Age.	Weight dressed.	Average.	Gain of weight per day during life.
				lbs.	lbs.	oz.
A	Oct. 10, '42	Dec. 17, '44	14 m. 7 days, or 433 days.	284 285 325	298	11
B	Oct. 22, '43	Do.	13 m. 26 days, or 421 days.	296 304 339	313	$11\frac{1}{12}$
C	April 10, '44	Do.	7 m. 27 days, or 241 days.	240 250 257	249	$16\frac{6}{12}$

"The pigs of class A had not the advantage of sucklings, the sow having died in the act of parturition. They are an encouraging example of what may be done by care and attention for a few days after birth. Each class was fed on the same kind of food, treated in the same manner, and attended by the same swineherd. B and C were weaned at 6 weeks old, and, till then, at no expense for food. As a further illustration of the truth of my hypothesis, let us, from the whole age of B, 421 days, and the whole age of C, 241 days, deduct the age when weaned, (42 days,) and we shall have the time fed of B, 379 days, and of C, 199 days. Again, let us, from the average weight of B, 313 pounds, and the average weight of C, 249 pounds, deduct the presumed weight if slaughtered when weaned, (20 pounds,) which gives the weight gained by B during the feeding, 293 pounds, and of C, 223 pounds.

C, 199 days,	229 lbs.	1 day=$18\frac{4}{12}$ ounces.
B, 379 days,	293 lbs.	1 day=$12\frac{3}{12}$ do.
Extra gain of C per day,		$6\frac{1}{12}$ ounces.

"But another and more common sense view of the subject is, that B was fed a little over 6 months, and gained 229 pounds. Difference for 6 months' feed only 64 pounds. Superadded to these facts, it must be admitted that B, from 6 months to 12 months' feeding age, consumed much more food than C consumed from 0 to 6 months; consequently, that B, during his whole feeding time, consumed more than double the quantity that C consumed during his whole feeding time. *Ergo*, that C was about 100 per cent. more profitable than B."

In the Mobile Daily Advertiser a statement, by way of calculation of the comparative advantage of raising stock in Kentucky and Alabama, is made respecting the profits of raising hogs in Alabama, which would seem to recommend this object of enterprise to the planters of that State. The writer bases his views on a farm employing 10 hands, and already stocked for operation. He says: "In Kentucky it would require a landed property of 325 acres; which would cost, at $15 per acre, $4,875. The ten hands would cost $5,000. Capital invested, $9,875. In this farm there would

be 300 acres of open land; 25 remaining wood, for convenience. The 300 acres of improved land would be cultivated in the following proportions: 50 acres in corn; 125 in oats and rye; 125 in clover and bluegrass; and 20 in artichokes. This would be the labor of 10 hands, which would only provide food sufficient to raise 300 hogs of one year old. The 300 acres of bluegrass, clover, oats, and rye, would receive 300 pigs, and pasture them from the 1st of May until the 1st October. It would then take all the artichokes and corn that would be made to feed the 300 hogs from the 1st of October to the 1st of May—seven months, (part of the corn having to be fed to the pigs while on pasture.) The hogs now one year old would weigh 150 lbs. each, and would make 4,500 lbs. of pork; which, at $2 50 per 100 pounds, would bring to the owner $1,122, sold in Kentucky. In Alabama it would require a landed property of the same number of acres as that of Kentucky. Let us now see if there is any difference in the profits of the capital invested. The 325 acres of land calculated for a farm of this description can be purchased in Alabama at $8 per acre, which would make a cost of $2,600. The ten negroes cost the same as in Kentucky, $5,000. The cost of the land and negroes in Alabama would be $7,600—$2,750 less than the outfit in Kentucky. Of the 325 acres there would be 300 acres in culture; 40 acres in corn and cow-peas; 125 acres in sweet potatoes; 25 acres in ground peas; and 100 in rye and oats. This would furnish food sufficient for 700 hogs. The 25 acres in ground peas would receive 700 pigs the 1st of September, and furnish them with food for two months, ending 1st November. The 125 acres in sweet potatoes would yield, at 250 bushels per acre, 31,250 bushels, which would alone feed the 700 hogs one year, allowing 4 quarts per day for each hog, which would be more than sufficient food for them one year. The corn, rye, and oats would be a reserve; and the Alabama farm of 300 acres in cultivation would yield 700 head of hogs of one year old, weighing 150 pounds each, making 105,000 pounds of pork; which, at $3 per cwt., would bring to the owner $3,150: showing a proceed of $2,028 more than the farm in Kentucky, with a capital of $2,750 less than was employed in Kentucky! The above is made upon a supposition that the hogs are to be kept in an enclosure and not suffered to run at large—to be dependant entirely on the product of the farm for sustenance. I have made the above estimate upon my own experience and information."

In the last report some observations were made in one of the appendices respecting the value of the *poultry* raised in this country. Increasing attention is now paid to this subject, and new kinds of fowls are introduced, and improvements are making every year as to breeding and feeding them. Many valuable suggestions are found in the agricultural journals, as well as in volumes especially devoted to the subject, respecting the methods of keeping them so as to be profitable. That it is a profitable business there can be no doubt. A single statement made respecting successful experiments will show this. In the Cultivator mention is made of one of these experiments, to ascertain if the raising of hens would be profitable, by James L. Cox, of Zanesville, Ohio. He says that in December and January, 1844–'45, he had 24 hens and 1 cock; the eggs hatched well in this proportion—110 set, hatched out 75 chickens. This was previous to July 1, 1845; and besides the eggs set, the hens laid in the same time 1,096 others. The grain eaten amounted to $4 25 for six months. He was prevented, by absence, from keeping an account for a whole year. W. Todd, of

Smithfield, Rhode Island, gives the following statement in the New York Farmer: "From the 1st of April, 1844, to April, 1845, my hens, 25 in number, have consumed 26 bushels of corn, at 75 cents per bushel, which amounts to $19 55, during which time I have sold in market 242 dozen of eggs, averaging 15 cents per dozen, which amounts to $36 30; no account being made of those used in the family. I have also sold $4 worth of chickens—in all amounting to $40 30. Here, then, I have left $20 75 clear profit." Philip Smith, jr., in the Cultivator for May, 1845 says: "The result for one year ending the 1st December, 1844, is as follows:

Poultry establishment.

Dr.		Cr.	
35 hens - - -	$4 38	88 hens - - -	$11 00
1 topknot cock and hen -	1 00	1 topknot cock and hen -	1 00
Grain for feeding - -	18 67	3,115 eggs - -	32 45
Rent of yard - -	15 00		
			44 45
Cost - - -	39 05		39 05
			5 40"

He also states that the stock hens had increased from 35 to 88, and that the increase is 53. His manner of keeping them is this: "I place a layer of saw-dust in a keg; then pack the eggs closely to each other with *the small end down;* over this place another layer of saw dust, packing closely to and between the eggs, where they do not touch, and so on filling the keg; then head it up tight and change it end for end every 24 hours." He says they will thus keep a year perfectly fresh and good.

A writer in the London Gardeners' Chronicle says that the following will be found an excellent method of fattening chickens: "Set rice over a fire with skimmed milk; let it boil till the rice is quite swelled out, then add a teaspoonful of sugar. Feed them three times a day in common pans, giving them only as much as will fill them at once. Let the pans be well washed, and set in clean spring water, that no sourness may be conveyed to the fowls, as that prevents them from fattening. Give them clean water, or the milk of rice, to drink. By this method the flesh will have a clear whiteness, which no other food gives. It is said that a portion of animal mixed with vegetable food causes poultry to thrive rapidly, but they should be confined to a vegetable diet for some time before they are killed. A quantity of charcoal, broken in small pieces, and placed within reach of the poultry, increases their appetite and promotes digestion." Some papers on the subject of poultry may be found in appendix No. 28.

In connexion with this general subject of poultry, also, we quote the following method of preserving eggs, from the Boston Cultivator, which deserves attention: "We have seen many recipes for preserving eggs, and have tried several without success. They have been saved in good condition, a year or more, in lime-water; but this requires much skill, as the lime-water may be too weak or too strong, there being a vast difference in the quality of lime. These nice chemical preparations may answer for those who are doing business on a large scale, but for common domestic purposes they will not answer. We put down some eggs in plaster of Paris last July, (1844,) in a close vessel. First, a layer of plaster, then a layer of eggs, not allowing one egg to touch another. On top we put a few inches of plaster, then covered the vessel over closely. The eggs were

fresh, being put down as fast as they were laid, or within three or four days. They were placed with the small end downward, and placed in a dry cellar. In another vessel we put down some at the same time, and in the same manner, with fine salt. Eggs from both lots have been tried every month from January; the last trial was on the 1st of this month, (June, 1845,) when the eggs had been put down nearly eleven months. They have all proved to be perfectly sweet and pure; and at the last trial, the white, in a raw state, had its natural taste, and those saved in salt had no perceptible taste of salt. The eggs looked, when broken, like recently laid eggs, excepting for the last three months. In those saved in salt, the yolk adhered to the shell; on this account, and as salt is liable to melt in a cellar, we prefer the plaster."

In one of the public journals, we find the following article on the egg trade of Cincinnati, which is worth perusal: "The egg trade of Cincinnati bids fair to rival the celebrated pork trade of that city, to an extent which will soon sink the *soubriquet* of Porkopolis to that of Eggopolis. It is, indeed, enormous—beyond computation. One firm alone (Townsend & Co.) during the first six months of this year shipped to New York 234 barrels of eggs; to Baltimore, 70 barrels; and to New Orleans 3,976 barrels! Each barrel contains 90 dozen; which makes the aggregate shipments 4,624,400 eggs! During the year ending as above, the egg trade of this firm amounted to $36,144 60. There are five other houses in Cincinnati engaged in the business. The foreign egg trade of Cincinnati the past year has amounted to 10,700 barrels; which is 963,000 dozen, or 11,556,000 eggs! The aggregate value of this trade for the year, according to the data here given, is $90,361 50. The business is a very hazardous one, owing to the great fluctuations in the New Orleans market. In the course of the past year, for example, western eggs have sold there as high as $22 per barrel, and as low as $3. In addition to this export trade, these establishments do also a heavy home trade. That of Townsend & Co. supplies regularly five steamboats with 36 barrels a trip; which, at 12 trips a year, is 432 barrels. It also furnishes constantly the consumption of several of the largest hotels, which use at least 260 barrels per year, and does a retail business amounting to not less than 33 barrels per year. These several amounts make 725 barrels to add to the 4,280 barrels shipped, which gives an aggregate of 5,005 barrels, or 450,450 dozen, as the annual trade of this one house. Besides this, the annual city consumption is estimated at 1,213,333 dozen. A further recapitulation shows the following results as to value:

Value of 10,700 barrels of eggs shipped from this port, at $8 44½ per barrel - - - - - -	$90,361 50
Value of 1,213,333 dozen eggs consumed in this city, at 8 cents per dozen - - - - - - -	97,066 64
Total annual value of the egg trade of Cincinnati -	$187,428 14

Among other objects which belong to the agricultural pursuits of our country, or connected with their domestic economy of the farm, may be mentioned *bees*. Great improvements have been made within a few years as to every branch of this business. Numerous hives have been contrived and patented, for the purpose of obviating the difficulties of hiving, to prevent the incursions of the bee moth, to save the swarms alive, and to subtract easily the honey when wanted. Many of them are constructed with

much ingenuity, and seem to answer valuable ends. In the Ohio Cultivator we find the following short article on the profit of bees, which seems to indicate that it is a branch of business which, under proper management, promises to repay those who engage in it: "As an instance of what can be done with a few swarms of bees, in good seasons and with good management, we give an extract from a statement furnished us, when travelling in this State two years ago, by Mr. D. B. Kinney, of Oberlin. Mr. Kinney commenced, in the spring of 1841, with five swarms of bees—four of them in Weeks's patent, and one in an old box hive. The debit and credit account stands as follows:

First year.	Dr.
To Weeks, for use of patent	$5 00
Cost of 11 new hives	16 50
Sheet-iron sides	40
Time and labor	6 00
Total	$27 90

	Cr.
By 11 swarms in hives, worth $7 each, (sold some at $8)	$77 00
Amount of honey sold	32 00
Honey consumed in family	5 00
Total	114 00
	27 90
Profit the first year	$86 10

The greatest amount of honey obtained from one hive was 60 pounds; the greatest amount from young swarm, 35 pounds. In the spring of 1842 commenced with 11 swarms.

Had 8 new swarms, worth (total)	$30 05
Amount of honey obtained, 515 pounds, worth	56 65
Profit second year, (averaging $7 85 per hive)	$86 65

"Greatest amount of honey obtained from one hive was 82½ pounds; greatest amount from young swarm, 39 pounds.

"The prices above stated, for swarms and honey, are those at which they found ready sale at the time. Mr. Kinney informed us that his bees had suffered very little from moths or other casualties, since the use of Weeks's hives. The honey has been of the finest quality, as well as extraordinary quantity. If any of his swarms appear weakly, Mr. Kinney puts two together in one hive."

An interesting letter of Mr. Kelly, on the subject of bees, will be found in the papers furnished by Mr. Ellsworth—appendix No. 1.

PREPARATION OF THE SOIL, SEEDS, &c.

The science of agriculture is advancing continually every year. The great principles on which tillage should be conducted, the economical re-

lations of one part of farming to another, are undergoing close investigation, and the elementary combinations by which fertility may be sustained or increased are studied, with accurate analyses of the soil, the crops, and the necessary aliment to be afforded. Discussions of a most interesting character are going on in the various periodicals to determine the comparative value of one method of tillage over another, and how far this or that preparation may answer for any particular portion of our country. We cannot, of course, enter largely into these various points, but it may be proper just to advert to some of them, and touch more or less lightly on others.

One of these is the *rotation* of crops. Of course these must vary according to the main object in view; but there can scarcely be a doubt that our farmers are, many of them, very negligent of the great principles on this subject. They go on cropping year after year successive yields of the same product, and yet they affect to wonder that, with perhaps increased diligence, they cannot obtain as large crops as when they begun. There is, however, no mystery in the matter. The soil calls out for a new supply of its exhausted materials, which some other crop might furnish, and which could be obtained through some other means of enriching it. On this subject Boussingault says: "That there is no absolute necessity for *alternation* of crops *where dung and labor* can be readily procured, is undeniable. Nevertheless, there are certain plants which cannot be reproduced upon the same soil, except at intervals more or less remote. The cause of this exigence on the part of certain vegetables is still obscure, and the hypothesis propounded for clearing it up far from satisfactory."

One of the marked advantages of alternate culture is, the periodic cultivation of plants which improve the soil. The main thing to be secured in the rotation of crops is such a system as shall enable the husbandman to obtain the greatest amount of vegetable produce in the shortest possible time.

The next point which we may notice is the practice of *extensive cultivation*. The consequence of this, in too many instances, is imperfect tillage and spare crops. Much ground has to be gone over to obtain results not more remunerating, if as much so, as were half the quantity of land employed. It might be a serviceable work if any one were to make an accurate calculation or comparison, embracing the additional fencing, the amount of additional travel to and fro, and time thus consumed in sowing, cultivating, harvesting, &c., the crop of the same number of bushels or pounds obtained on the larger farm so cultivated, and a smaller one tilled with the same amount of manure, &c. The loss thus suffered, it cannot be doubted, would prove a considerable item on many a farmer's year-book, were it carefully noted. There is, however, so much gratifying to human feelings in the possession of broad lands that we can hardly hope that, till our population has become really dense, our agriculturists will listen to the voice of science and true economy on this subject. A stinted culture, spread over numerous acres, may be the cause of lessened prosperity to many.

The subject of *draining* is one which is now commanding the attention of the agriculturists both of our own country and those abroad. It is maintained that the depth of soil may be thus increased. The system adopted and advocated is called the "frequent drain system," or "thorough draining system." The principle is, "the providing of frequent opportunities

for the water rising from below, or falling on the surface, to pass freely and completely off." Such is the statement of James Smith, of Deanston, Scotland, whose works on the subject are frequently referred to in the English agricultural periodicals. He says: "In the natural circumstances of the soil on the surface of the earth the drainage is extremely various, from that of the dry, light loam, incumbent on deep beds of open sand or gravel, to that of the thin, sterile crust of soil incumbent on massive beds of impervious till. In the former, there is no water springing to the soil from below, and whatever falls from the surface, in the shape of rain, is instantly absorbed, and passes through the sand or gravel to some outlet at a lower level. In the latter case, on the contrary, water, whether springing from below or falling upon the surface in the shape of rain, must either run slowly off over the surface, however great the distance, or, in the event of a horizontal surface, must remain stagnant till evaporated by the sun or absorbed by the atmosphere. On such a sub-soil a sufficient depth of active soil can never be long maintained; for even if trenched and enriched by lime and dung, it will bear but scanty and precarious crops; and if laid out for pasture, it will, in a few years, revert to its former thin crust, producing but the coarsest herbage. Some soils are incumbent on sub-soils partially or slowly pervious to water. Such, by judicious management, sometimes produce good crops in favorable seasons; but when much rain prevails the crops are neither bulky nor of good quality. Soils so situated are unfit for wheat, as the alternate frosts and thaws of winter, acting on the water in the soil, are sure to throw out the plants. When soil is immediately incumbent on open rock, especially on whin or greenstone, which is very open from its many fissures, the land is uniformly fertile." Professor Johnston says, as to the depth of the drain, that 30 inches is not too deep, and that the most intelligent and practical men are in favor of drains 3 feet deep. Great improvements have been made in Scotland by the drainage system. The following testimony to the utility of draining we take from an agricultural journal:

"*The magic effect of draining.*—A neighbor has a clay garden, which has sufficient inclination to carry off water; still, in spite of a large admixture of coarse manure, the sunrise would bake and crack it open in dry weather. Last spring he cut two deep ditches on each side of the garden, 40 feet apart. The result is, that the mechanical structure of the soil appears to be changed from a heavy tenacious clay to a light and porous loam, on which the drought of this season had no injurious effect."

Connected with this subject is another, viz: *deep or sub-soil ploughing.* The great importance of this has been thoroughly tested both in Europe and this country. In many cases it has proved a protection of the crop against the effects of the drought, besides enabling the farmer otherwise to obtain an increased crop. In appendix No. 29 will be found an account, by Rev. John Jaffray, of Dunbar, of an experiment on this subject, which is decisive. The practical conclusions, the author says, to be drawn from this experiment, are: "1st, that deep ploughing increases the produce; next, that as both portions of the land used in the experiment were opened up eighteen inches deep by the sub-soil plough for the crop of 1837, the full benefit of that operation is not obtained till the earth so loosened is again ploughed up. And the reason is evident; for it is then only that the soil is deepened, by an addition from the sub-soil with which it is intermixed, and rendered more fruitful. Lastly: If deep ploughing increases

the produce, it increases also the supply of vegetable manure; and a greater portion of manure, added to improved culture, must produce a progressive increase of fertility and of produce." Other instances are the following, which, as they are short, we subjoin from different journals: "*Deep ploughing.*—We have occasionally urged the importance of deepening the soil, by turning up and mixing with the surface small portions of the sub-soil, where its nature is such as to produce beneficial effects. We have known many instances of the beneficial effects of such a course. Dr. D. H. Robinson, of Farmington, Ontario county, New York, being compelled to prepare a piece of grass land for wheat, late in summer, ploughed it very deep —not less in any place than eight inches, but averaging nine or ten inches. This was thoroughly harrowed, with a small dressing of rotted manure, and sowed upon the inverted sod. The product was thirty-five bushels per acre, on land where twenty bushels are usually considered a heavy crop. Another very skilful farmer, of our acquaintance, finds so much benefit from the mixture of the sub-soil, that he considers a decided advantage would result, so far as raising wheat is concerned, if six inches of the surface of his land were entirely removed and carried off. Sub-soil ploughing would doubtless be useful, in such cases, to a certain extent; but we would more particularly recommend thorough trench ploughing—one plough to follow the first, so as to loosen and throw up the soil to the depth of at least one foot; the last team to be double, and attached to a strong plough."

From the Southern Cultivator.

Deep ploughing.—Mr. Camak: By your request, I give you the result of a trial made by myself, last year, in deep ploughing. Having received, late in February, several varieties of wheat distributed from the Patent Office, I immediately prepared a small piece of ground in the following manner: First, I ran a good turning plough, and followed in the same furrow with a long *scooter.* I attended to it in person, and am certain that the ground was thoroughly broken to the depth of both ploughs. The wheat, as I feared, was too late, and was destroyed by the rust. A thick coat of crab grass came up, and was suffered to grow until August, when it was cut and cured—making, on about a fourth of an acre, three cart loads of most excellent hay, of unusual length, measuring three feet and upwards. Indeed, it was the thickest and most luxuriant plat of grass I ever saw. The land was without manure; the season was unusually dry—so much so that I made but little over half a crop of corn. I had another piece of land left for the purpose of making hay, which I know to be a great deal richer, having had the drainings of the horse-lot for years. This received one single ploughing, but did not produce grass high enough to cut. These facts led me to reflect upon the cause of the difference between the product of the two pieces, without intending it as a comparative experiment. The result, together with the attending circumstances, satisfied me that the superior yield of the *unmanured* piece could be attributed alone to the *deep* and thorough ploughing it received in the spring.

Very respectfully, WM. RUTHERFORD, Jr.

Cowpens, Walton County, *March* 21, 1845.

Stirring the earth is likewise said to be very beneficial in dry weather. Experiments on this subject have proved this. And it is said that the dews settled on the newly turned earth, and imparted moisture; thus showing

that such an operation has a tendency to attract moisture to the roots of plants which lie buried in the earth. It is thought, also, that by moving the surface and keeping it in a light and porous state, it is enabled to *resist the heat* of the sun's rays.

A writer in the London Agricultural Gazette, writing on this subject, says: "Pulverization of the soil increases the capillary attraction, or sponge-like property of soils, by which their humidity is rendered more uniform. Gravels or sands retain little or no water; while stiff soils, as clays, which have not been opened by pulverization, either do not absorb water, or when by long action it is absorbed, they retain too much. The depth of pulverization must depend upon the soil and sub-soil. In rich land it can scarcely be too deep, and even in sands, unless the sub-soil contains particles noxious to vegetables; but very dry sands, if the season is hot or dry, should merely be stirred, otherwise the great evaporation of moisture, which would take place by deep pulverization, would render them too dry for the vigorous growth of plants. The grand object of deep pulverization is to cause the soil to retain heat and moisture, so necessary to the healthy growth of vegetables of every description. Some proportion ought to be observed between the depth of the ploughing, the nature of the soil and sub-soil, and the quantity of the manure annually spread."

In connexion with the preparation of soil may be mentioned the account of prairie cultivation, which is given by the late Commissioner of Patents, and which may be found in the appendix No. 1, including such papers as he has furnished to the office for this report.

The experiments respecting the *electro-culture* of plants do not seem to have resulted favorably, and the idea of its proving of any value is now discarded by the best agriculturists, both of this country and abroad. Professor Solly stated to the meeting of the British Association the result of a series of experiments, which in some cases seemed favorable, and in others not. "Out of a series of 55 experiments on different seeds, 21 appeared in favor of electricity, 10 against it, and 25 showed no effect whatever; and in carefully counting the whole number of seeds in the entire series, there were found 1,250 of the electrified, and 1,253 of the non-electrified. In conclusion, Professor Solly stated that he felt doubtful whether the effects observed were really due to the influence of electricity."

In the Electrical Magazine for October, the experiments of Professor Solly are also confirmed by the Rev. Mr. Sidney's statement. A process of quickening the germination of seeds, however, is referred to in the following extract from one of our public journals:

"*Important to agriculturists—electricity.*—A communication was read at the late meeting of the Royal Agricultural Society, England, from Mr. La Beaume, in relation to experiments in quickening the germination of seeds, invigorating their plants, increasing their fecundity, and improving the quality of their products, by means of elecricity. 'The means I have employed,' says the writer, 'are not atmospheric electricity, galvanism, or electro-magnetism, which cannot apply, but electricity developed by a machine of adequate powers, and by a simple, peculiar, and effective process, easily understood and easily used, with very little manual labor. The time required is on the whole about half an hour, and 1,000 bushels of wheat, or any other grain, can be electrified as easily as an ounce, at the same time. I beg also to announce that this, my process, applies equally to the resuscitation of the impaired vitality of old as well as bad seeds, to the revivification

of withering plants, and to the increase of the quantity and quality of their fruit. In order to a more extended trial, and to the establishment of the facts I have communicated, if several members will send me some packages of turnip and other seed I will freely and cheerfully electrify and return them in a day or two, so that success may be proved by an impartial trial under your auspices; and I shall neither seek nor receive any other reward than your approbation, and the satisfaction of diffusion of practical knowledge for the public good.' Further trials by Messrs. La Beaume, Earl of Essex, and others, were promised at the next meeting. We doubt not any American can readily try the experiment from the above notice. Its importance certainly should prompt them to do so at once."

A discovery, which it is thought may be useful to florists, &c., has been made in England by the secretary of the Royal Polytechnical Society, and which is both curious and interesting. It relates to the germination of seeds under colored glass. "By this it is proved that the yellow and red rays are destructive to germination; while under the influence of violet, indigo, or blue light, the process of germination is quickened in a most extraordinary manner. The *rationale* is, that every beam of light proceeding from its solar source is a bundle of different colored rays, to the absorption or reflection of which we owe all that infinite diversity of color which is one of the greatest charms of creation. These rays being known to possess different functions, the light which permeates colored glass partakes of the character of the ray which corresponds with the glass in color. Thus blue glass admits the blue or chemical rays, to the exclusion of others; yellow glass admits only the penetration of the *luminous* rays; while red glass cuts off all but the heating rays, which pass it freely. This affords a very easy method of growing plants under the influence of any particular light that may be desired."

On the *quantity of seed* to be used for an acre, there exists a diversity of opinion; the question of thin or thick sowing both having its warm advocates. By the subjoined table, prepared by the editor of one of the agricultural journals—we believe of the Cultivator—it will be seen that there is less seed used to an acre with us than in Europe. How far this may affect our comparative crops, may be worthy of attention.

	GERMANY.		ENGLAND.		UNITED STATES.	
	Seed per acre.	Product.	Seed per acre.	Product.	Seed per acre.	Product.
Wheat - - - - -	2½ bushels	25 bushels	2½ to 3½ bushels	28 bushels	1 to 1½ bushel	18 bushels.

A number of articles on the general subject of cultivation may be found in appendix No. 29.

MANURES.

The great facts respecting the operations of *manures*, it is believed, are now thoroughly established. The constituents of soils, of various grains and vegetables have been determined, and the proportions, in many cases, may be considered fixed with all the precision of the deductions of science. The theory advocated by one or another may not be free to every mind from objections; but the bearing of particular substances in the production of certain results is readily admitted. It is considered an axiom, it is believed, that there are certain substances which, when found in the soil, render it more than ordinarily fertile; and on the other hand, that there are certain things in the different kinds of plants or vegetables which render it necessary that they be allowed a particular adaptation of the soil, and its auxiliaries, in order to be successfully raised. The great object in relation to manures now seems to be to bring as much efficacy as possible into the smallest compass. Ammonia is admitted to exercise a great influence in production; and to fix this so as to derive its fertilizing power to the crop, is one of the ends proposed.

In preparing and preserving manures, as it has been said, the rational objects to be obtained are, first, to preserve and collect all matters containing the organic or inorganic constituents of the crops which we are about to raise; and, secondly, if the matters so collected are in such a state as not to be immediately available as food for plants, to render them so by artificial means. In these latter cases fermentation is the great operation, and this may be either hastened or retarded, accordingly as care is or is not taken in the disposition and arrangement of the materials, and in adding the necessary substances as helps in the process. Various methods are proposed, according to circumstances, to effect the object. Both science and practice have determined some general rules; but exceptions, too, will exist, so that it need not be thought surprising if experience sometimes runs counter to the views of even the wisest in these subjects. No doubt, also, in many cases, on closer scrutiny, it might be found that the conditions were not exactly similar; and that, perhaps, the failure may be the result of a deficiency, or an excess which has been overlooked, or considered too trifling to be taken into the account; but, for all practical purposes, the case may be termed an exception.

The opinion seems to be very generally entertained that the *liquid* manures, which have been too generally neglected, hold a very important place in the means of enriching the soil, which are at the command of the husbandman. The principle is universally maintained, that all manure must be in a soluble or decomposed state, in order to act either proximately or indirectly on the plant or soil. Though applied in a solid condition, yet, by moisture, &c., it must be made to give out its fertilizing properties, or it is vain to look for success from its use.

Professor Liebig, who is considered one of the ablest writers of the present day on the action of manures on plants, it is stated, "has discovered certain compounds, &c., which are of such a nature that different states of moisture in the atmosphere, or different localities, will not diminish their efficacy." In his pamphlet, he declares: "I have found means to give

to every soluble ingredient of manure, by its combination with others, any degree of solubility, without altering its effect on vegetation. I give, for instance, the alkalies in such a state as not to be more soluble than gypsum." "The reason why, in certain years, the best and most plentiful manuring is scarcely perceptible, is, that during the moist and rainy springs and summers the phosphates, and other salts with alkaline bases, as also the soluble ammonical salts, are entirely or partly removed. A great amount of rain or moisture removes in the greatest quantity the very substances which are most indispensable to the plants at the time that they begin to form and mature seeds." Again: "I have succeeded in combining the efficacious elements of manure in such a manner as that they will not be washed away; and thus efficacy will be doubled." He states that the following may be considered as the constituent elements of a powerful manure, applicable to all sorts of soils, viz: *phosphate of lime*, found in bones, &c.; *phosphate of magnesia*, which it is well known enters largely into the composition of the grains. *Alkaline phosphates* also are important elements of the seeds of grass, peas, beans, &c. The *Alkalies, (potash and soda,) sulphate of potash, chloride of potassium, salts of lime, salts of ammonia, decaying vegetable matters*, which contain carbon, are also useful. He thinks that an artificial manure may be formed to supply the place of guano. We have placed his whole letter in the appendix No. 30.

That he is mistaken in the probable speedy exhaustion of guano, we think is evident from the official report made to the Peruvian government in 1842, and published at Lima, under the authority of the treasury department. This report, it is stated, gives the result of a survey made by the order of the Peruvian government of three islets near Pisco, in latitude about 14° south, called the *Chinchas*, where is found one of the *many* deposites of guano which abound on the coast of Peru and Bolivia, to an extent of 800 miles. "The superficial extent of the deposites the surveyor found to be 1,554,406 square varas, (33¼ inches English is a vara,) and the depth to vary according to the irregular surface of the rock upon which it is based; but making liberal allowance for the points of rock rising above the bed of the general mass, he calculated an *average depth* of 60 varas, which gives the sum total of 93,264,360 cubic varas. The cubic vara of guano, as found in these deposites, weighs more than half a ton; but taking no account of the excess, we have here 46,632,180 tons, which, if extracted at the rate of 50,000 tons per annum, would last more than 900 years; and valued at $50 per ton, amounts to $2,331,609,000, a sum such as no mine has produced."

There are various other places where guano is found; but all the different kinds are not of equal value. The Peruvian and true Bolivia are esteemed the best: after these the first quality from Ichaboe; then the second quality from Ichaboe, and that from Saldanha bay. The Chilian is an inferior kind. The deposite at Ichaboe is mostly exhausted. It is stated that guano has been found on some of the islands in the gulf of St. Lawrence; and it is conjectured that it may be yet found on the coast of Labrador; also of Florida.

The principal ingredient which gives guano its great fertilizing power is ammonia; though there are other elements also, and animal matter, to be discovered by analysis. It has been thoroughly tested in its application to various descriptions of crops. The agricultural journals abound with proofs of successful trials, and the books and treatises on manures also

furnish similar evidence. One of the best pamphlets on the subject, detailing in plain language the experiments made in different crops, is that of Mr. Teschemacher, of Boston, called "*An Essay on Guano.*" Mr. Teschemacher is a strong advocate for its use, and offers many valuable suggestions, which we should like to transfer to our appendix; but the work being a copyright one, precludes such a free use of its pages, and we have not time now to condense its results. We have placed, however, in the appendix No. 30, a letter of J. P. Norton, from the Am. Agriculturist, which relates to guano and other manures. Also extracts from a letter of Mr. Pickett to the National Institute on the guano of Peru. A remarkable case of death produced by the inhalation of guano, furnished by the attending physician, will also be found quoted from a public journal in the same appendix, No. 30. The consumption of guano in Great Britain up to the 1st of July, 1845, is thus stated: "*Consumption of guano in Great Britain.*—In 1841 it amounted to 500 tons of Peruvian; in 1842, to 2,000; in 1843, to 5,000; in 1844, to 10,450 of Peruvian and 16,000 African; 1st July, 1844, to 1st of July, 1845, of Peruvian and African 135,550 tons—value, at £6½ average per ton, is £881,075, or $4,291,160; and the stock on hand (140,000 tons) $4,368,000; making $8,659,160 expended in four years for one species of manure." In the London Gardeners' Chronicle for June 28, 1845, under the title "*What will a ton of Guano produce,*" we have a computation, said to be furnished by a correspondent, as follows: Four cwt. of guano per acre will produce of turnips 25 tons; one ton, therefore, will produce of turnips 125 tons, and 125 tons of turnips will produce 31 tons of dung; which, at the rate of 2*s.* 8*d.* per ton, will bring £4 2*s.* 125 tons of turnips will give 1,500 pounds of beef—at 6*d.*, amounting to £37 10*s.* Produce of 1 ton of guano, £41 12*s.* Again: Five cwt. of guano will produce of potatoes 10 tons; 1 ton of guano will therefore produce 40 tons. 40 tons of potatoes will give £50. Produce of potatoes, £50. Produce of turnips, £41 12*s.* Balance in favor of potatoes, £8 8*s.*; sufficient to purchase a ton of guano. But to show the value of guano in its true light, on a broader view, we will suppose that there are few farmers in this country who do not grow their five acres of green crops. To effect this with dung alone it will require (at 40 yards to the acre) 200 cubic yards, which most farmers can manage to raise on the homestead. Five acres of turnips, at 25 tons to the acre, will give 125 tons; yielding, as above, £41 12*s.* The same manure distributed over 10 acres, along with 1 ton of guano, (20 yards dung and 2 cwt. of guano per acre) at a cost of £10, will yield double the quantity of turnips; which turned into beef and manure, will yield, at the same ratio, £83 4*s.* The profit arising from a ton of guano, after deducting £10 for its price, is £31 12*s.* This is the profit from one crop only, on five acres."

It is well known that guano is the dung of fowls, and our farmers therefore have it in their power, by saving the manure of their poultry yards, to avail themselves to a considerable degree of the benefits of this special fertilizing substance. A bushel of hen's dung will have a decided effect on their vegetable crop; and, as it may be applied to advantage in a liquid state by adding water, it can be made to go further.

Some of the poudrette manures are also valuable for the same purpose. In the appendix No. 30 will likewise be found the account of Mr. Pell's experiments with prepared manure, read by him before the American Agri-

cultural Association, and which we have taken from a late number of the American Agriculturist. In the same appendix we have likewise included some other papers on the subject of manures, which, as will be seen, we have taken from various sources. Had we sufficient time and space, we might insert a great variety of experiments, which we have noticed on record, as to the efficacy of different manures. Bones, salt, charcoal, nitrates, anthracite, and other ashes; lime, and a great number of other articles, are commended for particular purposes. Indeed there is scarcely any refuse which may not be made valuable for this object; and our farmers have yet to learn the secret of the wonderful powers at their command, if they will only read and reflect, and apply the knowledge they may thus obtain as to fertilizing their lands.

The following useful suggestions we take from the American Agriculturist. It applies to other cities and towns besides New York. "We will make a simple suggestion to the public, without charge. Insert under each aperture of a privy, drawers made of wood, iron, or metal, two feet wide, two feet deep, and any required length, with handles at each end, so that they can be as easily drawn out and handled as those of a desk. Put into these drawers peat, mixed with a little plaster of Paris, or charcoal dust, mixed with plaster, to the depth of six inches or a foot. Thus arranged, not the slightest unpleasant smell would arise from the privy; and, every week or fortnight, carts, with tight boxes in them, should call at the house, and the drawers be emptied into them. In this way the yards would be purified of a shocking nuisance, and vast quantities of poudrette could be weekly manufactured, for which any company could well afford to pay the city of New York $100,000 per annum. Oil of vitriol diluted in water, at the rate of five pounds to a barrel, poured into a vault of moderate size, will completely disinfect it. Where drawers are placed to catch the fæces, as directed above, no other liquid but urine should be emptied into them. Boussingault estimates the solid and liquid excrements of a man at 618 pounds per annum, containing 18 pounds of nitrogen—a quantity sufficient to grow 836 pounds of wheat."

From other public journals: "Lord Torrington has just issued from the London press a small work 'on the agriculture of Kent,' in which he says that for ten years he has never failed to grow a good crop of Swede turnips 'by invariably putting charcoal in the drills with the seed.' He pulverizes the soil very fine before planting, and scatters (after the seed are in the ground, and before they are up) a top dressing of common salt, at the rate of 200 pounds to the acre. Wood ashes, bone dust, and guano, are all used in Kent for both turnip and wheat crops. Ashes, coal saturated with urine, and salt, are the cheapest and most valuable fertilizers to be had in this country."

"*What next?—Sugar recommended as the cheapest and best manure for turnips!*—A writer in the English Mark Lane Express of the 5th of May, says: 'Farmers are busy in preparing ground for potatoes and turnips, and the fallows generally are in a forward state. This is the period now, and from now till June, for the farmer to be on the alert. If he loses his turnip crop it is more his fault, in the majority of cases, than any controlling cause. His motto should now be, to keep his soils moist by compression; and the seed is certain to germinate, and go on, too, if he will but supply the young plant with the necessary food. Sugar will, (now the price is reduced) I have no doubt, be extensively used. I speak from ex-

perience when I say that, of all extraneous manures, if one it may be called, it has produced more visible effects in the least space of time than any other I ever used, and is strictly what the turnip plant requires in the first stage of its growth. I would strongly recommend it to be tried on a small scale, mixed with ashes.'"

Again, from the Boston Cultivator, which derives it from an English source: "The waste of manure from the farm-yard (especially the liquid portion) has of late been the subject of frequent remark. One of the best constructed yards in the country, for the purpose of securing *all* the manure raised, is that of R. Spooner, esq., M. P., of Brickfields, near this city, who, our readers are aware, has a fine farm of from 150 to 200 acres in the highest state of cultivation. This farm-yard has excited the admiration of a correspondent of a western paper, who states, upon seemingly good authority, that Mr. Spooner has not expended a shilling for manure for many years, (with the exception of a trifling sum for the lately introduced novelties, by way of experiment,) but has sold much farm-yard manure to his neighbors, not knowing how to dispose of it on the farm. Although he does not possess an acre of watered meadow, he has generally hay for sale. In the centre of Mr. Spooner's farm-yard is the manure pit, six or eight feet deep, covered by a roof and surrounded by a dwarf wall, so as to prevent the possibility of any water getting in. It is of the same form as the yard, but leaving sufficient room for a carriage way between it and the building. It is entered by an inclined plane, wide enough to back in a cart opposite the approach to the yard. Into this pit the dung from the stables and cow-houses is promiscuously thrown; in the middle of the side contiguous to the latter is a well and a pump, which receives the drainage therefrom and the stables, which is pumped up and spread over the manure by a shoot. The surplus liquid that is not absorbed is drawn off by means of a drain into a receiving well in the stock-yard, where it is pumped up into the liquid manure cart and drawn out on the mowing ground as soon as the grass is cut, until such time as it is laid up again; in the spring it is otherwise disposed of, on headlands and heaps of soil. Liquid and solid manure, prepared in the way above described, preserves all its nutritious qualities; the one is not diluted with water, and the other is not suffered to deteriorate by overheating, and is of treble the value of that made in the common manner."

Again: "Mr. Brown finds that plaster, applied to his manure heap and his stables, has added 50 per cent. to the strength and value of his manure. He sows plaster over his barn-yard once a week. Mr. Brown has used salt as a manure with great benefit. He sows it broadcast upon wheat and grass, at the rate of from three to five bushels per acre. On grass, he would sow it in the fall; for wheat, he would sow it just before the wheat is sown. He found that three bushels of salt to the acre on his wheat field, occasioned an increase of seventeen bushels of wheat to the acre over that which had no salt. The soil was a strong loam, with a stiff sub-soil. Mr. B. had not tried salt to kill wire-worms."

"M. Boussingault made a communication relative to a new ammoniacal manure. Having remarked that magnesia, the basis of which has always been regarded as injurious to vegetation, was found in the ashes of all vegetables, and in a proportion in accord with the quantity of phosphorus also found in the ashes, and of that of the azote, which enters into the composition of plants, he was led to infer that vegetables must assimilate with

ease and advantage the ammoniated magnesian phosphate. Being desirous of verifying this by experiment, he planted, on the 1st of May last, some grains of early maize, which had already germinated, in two series of pots, into the half of which he had poured 15 grammes (about half an ounce) of double phosphated salt for each pot. The two series of pots were then placed in the open ground. During the first twenty-five days, the vegetation was the same with both series; after that, there was a difference in favor of the pots which had been watered with the phosphate. On the 25th July, the plants in them were double in height those of the other series, and the diameter of the stems was two-thirds thicker. By the 25th of August, the proportion had diminished: the height of the plants watered by the phosphate was then only one-third greater, and the size of the stems double. At the moment of their coming to maturity, the phosphated plants bore two sound ears and one that had failed to come to maturity; the other plants had only two ears each, viz: one complete and one that had failed. This was not all; each grain of the ears of the phosphated plants was double in weight to that of the non-phosphated plants. M. Boussingault concludes, therefore, (and with great reason,) that the salt in question may be used with great advantage as an artificial manure."

Mr. Weller, of North Carolina, in one of his communications to the North Carolina agricultural paper, has the following recommendation for improving the land:

"I observe, ere I close, that one most effectual means, as I have found by years of experience, to make land better, is that of covering small grain, immediately after sowing, (but if wheat, when up, and at leisure, during winter,) with pine leaves or straw from the old field or woods an inch or so deep, spread over evenly. I have frequently doubled my crops of oats, wheat, and rye, this way. On that part of a field thus covered and shaded, twice as good as the part not covered. Besides, the ground, by the after decomposition of that vegetable matter, is gradually improved. And one grand advantage of this covering of small grain is, that even sandy land (if sufficiently rich at least) may have a clover crop thereon, sown with or after the small grain, (if wheat, in spring, after covering in winter,) without the usual danger of being burnt out by the hot sun and dry weather of summer. Indeed, I have found such repeated covering equivalent to marl, and less trouble of putting it on. Where pine straw is not to be had, wheat straw or other litter is equivalent, and perhaps better for wheat, on the principle lately discovered, that the straw or litter of any kind of plant makes the best manure for the same. Hence, cornstalks are the best litter for corn, if managed as before stated." In connexion with this subject of manures, it may not be inappropriate to subjoin the following statement of the analyses of different crops, as they show the constituents required for their production. With comparative tables of analyses of manures and soils of various description, arranged correspondingly, the farmer would be much aided. We have not been able to lay our hands on any such tables, or found opportunity or materials with which to compile them; though, perhaps, by long search they might possibly be obtained from a great variety of publications. Sprengel has the most extensive analysis of soils and manures of which we know; but we do not find all we seek there, nor in Thaer, Veit, or Boussingault, and other authors whom we have consulted. In Burger's Economy of Farming may be found many tables, as to soil,

from Schubler and Sprengel. We take the following from the New England Farmer, furnished by Mr. Teschemacher:

"The English agricultural societies have voted a considerable sum of money for the purpose of analyzing the ashes of plants, none of the analyses yet made having been found satisfactory; and those of Sprengel, as Liebig justly observes, being altogether incorrect. In the mean time, however, two German chemists, Messrs. Fresenius and Will, in the laboratory of their great master at Giessen, have undertaken the analyses of ashes of seeds and plants, and have recently published an account of them, with the methods pursued, and the precautions taken. Some of their observations and results I propose to give, as I find by the last number of your paper that this information is desired. It would be misplaced to give here the beautiful processes by which the analyses of these gentlemen were performed; the *results* will, no doubt, be more satisfactory. The first I give are 5 out of 10 specimens of tobacco grown in Hungary, on land in various districts, which had never been manured, and on which this plant had been some time cultivated. And in these we shall see illustrated the beautiful law of substitution of one base for another, which may be wanting in the soil, as laid down by Liebig. It will be observed that as the quantity of potash decreases, that of lime increases; the former being exhausted out of the soil, is replaced in the plant by the latter, which is in plenty. There is no doubt, however, that this substitution must cause a difference in the quality, and is, therefore, a subject worth studying by the tobacco planters of this country. I give only those made after deducting the carbonic acid, the charcoal, and the sand.

Analyses of five specimens of tobacco.

The reason why the charcoal and the carbonic acid are left out, although they are given in previous analyses, is, that they may be considered, for our purpose, as accidental ingredients, inasmuch as in most the quantity depends on the texture, on the quantity and quality of the bases they originate in the combustion, and depend much on the degree of heat used. The ashes of seeds, so far as their composition is known, consist, like those of the blood of man and of other animals, chiefly of the phosphates of the alkalies and the alkaline earths. The curious fact, moreover, has been lately observed, that the phosphoric acid is not, in all seeds, combined with the same number of equivalents of fixed bases. The seeds of leguminosæ and the coniferæ contain tribasic phosphates, (earth of bones is a tribasic phosphate.) The seeds of cerelia, also buckwheat, hemp, and linseed, contain bisadic phosphates. This relation is maintained when seeds are grown in different localities. The quantities of oxygen contained in the bases of these seeds, leaving out the unimportant sulphates and chlorides, are so nearly alike, that it is evident that the law of substitution of bases applies also to the phosphates.

"*Analysis of maize, by Letellier, at Bechelbronn.*—Potash and soda, 3.08, and loss; lime, 1.3; magnesia, 17.0; phosphoric acid, 50.1; silica, 0.8. Total 100."

In this connexion, we may also add some articles relating to the methods of planting various crops together, &c. We have already furnished some examples under the head of an individual product. But there are others which we deem worthy of notice, and which appear to come in better with this part of the report than in any other. We shall throw a portion of them into the appendix No. 29. The account rendered by John Jones, of Wheatland, Delaware, respecting his farming operations, is an interesting

* Phosphate of lime.

one. His farm, to which he removed on the 4th of March, 1834, and which contained 360 acres in Delaware, and 30 acres in Maryland, when he entered upon it was in a very poor state, and scarcely paid six per cent. on the purchase money. In 1837 he commenced liming it, and, up to 1839, put on 12,000 bushels of lime, at a cost, at the kilns, of 20 to 22 cents per bushel. By 1840, he saw and felt the good effects of the lime, and determined to go on and complete the first dressing of all his arable lands, as well as another farm of 380 acres. He purchased 10,000 bushels of lime, at 17 cents per bushel. Previous to 1840, he had sown clover and other grass seeds pretty freely—one year as much as 45 bushels; and the same year he purchased 20 tons of plaster. At first he got but a poor return even for his lime, as he supposes, for want of vegetable matter; but when his clover had grown so as to make a swath or lay for turning under, his crops began to increase even beyond his expectation. The crops for the year 1844, which closed with his best wheat crop, were all got out and sold by the 25th of July, producing the following results: Oat crop, light, not many sown—crop sold for $209; rental share, $104 50. Corn tillage, large—97 acres, including an orchard of four acres, not well tilled, produced 3,000 bushels; rental share 1,500 bushels—at 40 cents, $600. The wheat crop amounted to 2,820 bushels, exclusive of brock or rakings; the rental share one-half, or (say) 1,410 bushels—at 90 cents, $1,269. It was grown on two fields—one of which of 97 acres, a clover lea, well turned under, produced 1,872 bushels, exclusive of brock; which would have made this field amount to over 20 bushels to the acre, $1,973 50. Add 64 bushels of brock, at 90 cents per bushel, ($57 60,) and we have $2,031 10. His other field of wheat contained about 60 acres. The product of this field was 948 bushels, exclusive of rakings; or, had they been included, the yield would have exceeded 16 bushels to the acre. This field had been hard cropped, for the wheat followed corn; which corn had followed wheat stubble the year previous, without clover or manure. Indeed, this field has had nine crops in 12 years, with but little manure at any time, it being farthest from the farm-yard, and his place is poor land near by. The principal help this field had was 40 bushels of lime to the acre, put on in 1838, and two crops of clover turned under; and on a part of the field a crop of oats was turned under that had been injured by the hail storm of 1840. The rental value of these three crops of oats may be set down at $2,031 10; allowing, according to usage, half of the grain for rent; and this pays the interest, at six per cent, of the capital of $33,850. The original cost of the farm was $4,100. The cost of the lime, 40 bushels, was long since reimbursed. Including his stock, &c., he considers his farm yielding a rent equal to the interest of $100 per acre; and his crops have been gained by ordinary good tillage, a rotation of crops, and 50 bushels of lime. In the London Gardeners' Chronicle for August 30, 1845, we find the following method, by which, on three acres, to keep four cows all the year: "Plant one acre to potatoes—the produce should buy three tons of hay; equal, for November, December, January, February, and March, to ten pounds per cow each day. Plant one-fourth of an acre to mangel wurzel, one-fourth of an acre to carrots, and one-fourth of an acre to parsnips: the first will give you 25 pounds; the second, 15 pounds; and the third 30 pounds per cow, each, during the same time; but in feeding during winter you would need to keep the mangel wurzel untouched till March or April. This will more than provide for you during winter. For summer, sow one-fourth of an acre of rape, and one-fourth of rye, as

soon as you have dug that extent of your potatoes. These will be ready for March and April use; the ground on which they stand will come in for mangel wurzel and carrots. Your third acre may be planted—half of it to lucerne, and the other half may be sown to vetches, at successive sowings, in October, November, March, or April. These, with what may be left of the hay and mangel wurzel—and some of the latter will remain as late as June—will last you from April to October. You should cultivate all these with the spade, and your success will depend much upon your care and proper application of the manure." For this country very probably the above might need modifications.

A mode of raising corn, potatoes, and pumpkins in alternate rows, is thus described in the American Agriculturist, by one of its correspondents: "Mr. Muir, of this town, gave me an interesting account of an experiment made by himself in 1837, in planting one acre of land with corn, potatoes, and pumpkins, which was as follows: The land was ploughed from six to eigtht inches deep, well harrowed, and a light coat of manure spread on, and harrowed in well. The land furrowed lightly 2½ feet apart, and planted one row of corn, and the next potatoes, alternating them to the sixth row, which he planted with pumpkins. Thus every other row being corn and potatoes, except the sixth row, which was pumpkins, throughout the field. The corn in the rows stood only one stalk in a place, in this manner: 6 14 8 16 6. One cornstalk, and then a space of six or eight inches to another; then a space of 14 to 16 inches. The potatoes and pumpkins were planted as thick as they would bear, but he did not describe the manner. The amount of produce from the acre was as follows: 187 bushels of corn in the ear; 153 bushels of potatoes; and 100 cartloads of West India pumpkins. He has since followed a similar course, and is satisfied that this is the best way for him to get the most profit from his land.—E. P., *Essex county*, *N. Y.*, *March* 25, 1845."

Some other useful remarks on the subjects of cultivation in general may be found in our appendix No. 29.

SURPLUS, AND MARKETS.

In some of the States the amount of provisions raised on their own soil is not sufficient for the consumption of their population, and they of course must depend on others to supply them. But they, in their turn, have products of various kinds to give in exchange. This creates a brisk domestic trade, the results of which are seen all along our coast, on our inland seas and the different rivers, canals, and railways connecting the various points of commerce in our land. The surplus, too, seeks an outlet abroad, and becomes our medium of commerce abroad. It is unnecessary to attempt to trace out its courses. We refer to the appendix, Nos. 31, 32, for a number of tables, &c., which will illustrate the relation of our agricultural products to our foreign trade. We add here a few items which may be useful, as showing the amount of our resources, which we have taken from different public journals:

"*The exports of Ohio for* 1845.—The Cincinnati Chronicle says: We have before us the shipments from Cleveland, Ohio, and Cincinnati, for the year 1845, to the last week. As the season is nearly closed, we can give a tolerably accurate view of the exports of 1845 from this great agricultural State. It must be remembered that, in estimating the exports of a year, commencing the 1st of January, we do not get precisely one season's pro-

duction, but only one season's transportation. The production belongs to both—to the last and the present season. The shipments of the surplus of flour this year will be very nearly as follows, reducing the wheat to its equivalent in flour:

"Cleveland, 450,000 barrels; Cincinnati, 150,000; Toledo, 100,000; Milan, Sandusky, &c., 150,000; Marietta, &c., 40,000; Portsmouth, &c., 30,000. Total, 930,000 barrels. The other articles we estimate in money, thus: Flour, in all 930,000 barrels, $4,000,000; pork, in all $3,500,000; cattle and beef, $500,000; wool, (2,000,000 pounds,) $500,000; cheese, (5,000,000 lbs.,) $300,000; manufactures, $3,000,000. Total, $11,800,000. We think these results are under-estimated, and that there are miscellaneous articles enough to make the net surplus in value $12,000,000. The flour product is $2,000,000 less than it would have been had the last two harvests of wheat been good ones."

The following exhibits the amount of grain and flour transported in 1845 on the different lines of the Pennsylvania improvements named:

	Flour, bbls.	Grain, bushels.
Chesapeake and Delaware canal - -	31,585	1,314,891
Tidewater canal - - - -	90,187	983,260
Columbia railroad - - - -	188,993	261,594
East division Pennsylvania canal - -	115,950	87,332
Schuylkill navigation - - - -	74,131	349,680
Total - - - - -	550,846	2,996,757

Comparative statement of the amount of flour and meal exported from Philadelphia during the last three years:

	Flour.	Rye flour.	Corn meal.
1845 - - -	200,642 bbls.	17,132 bbls.	413,195 bbls.
1844 - - -	296,433	21,903	101,236
1843 - - -	162,847	52,025	108,166

"From the Buffalo Commercial Advertiser.

"*Annual trade of the canal.*—By the established standard of valuation, on property arriving here, and on that seeking the seaboard, it is found that the interior, during the past year, has overdrawn her account; or, in other words, has the balance of trade largely against her. The class and valuation of property arriving and clearing by the canal, in 1845, has been as follows:

	Arriving.	Clearing.
Of the forest - - - - -	$77,895	$1,707,136
Agriculture - - - - -	146,566	7,060,545
Manufactures - - - -	1,207,510	400,853
Minerals - - - - -	59,259	820,494
Merchandise - - - -	15,134,014	44,278
Sundries - - - - -	263,048	
Total value - - -	$16,888,382	$9,502,306
Total tons - - - - -	144,413	243,673

Balance against the west in 1845, $7,386,076.

"The up and down freight by the canal at this place, its valuation, &c., for a series of years, has been to the annexed extent:

	Up freight.		Down freight.	
1840	78,261 tons	$9,996,696	130,465 tons	$5,512,326
1841	86,243	10,302,144	170,809	8,199,142
1842	76,747	8,009,330	174,030	6,884,156
1843	116,601	14,570,120	224,106	9,139,756
1844	139,520	15,965,000	243,086	8,840,030
1845	144,414	16,888,380	243,673	9,502,366

"A change in the classification of some commodities going east, renders explanation necessary. Heretofore butter and lard went forward as one item; and bacon, hams, &c., passed as pork, and were reduced to the barrel standard. This year they have been kept separate. The amount in bulk cleared for the Hudson this year was 1,218,810 pounds—equivalent to 6,000 barrels. So that, by adding this with the quantities of pork shipped this season, it leaves a deficit of 18,130 barrels, as compared with 1844. Hemp is now becoming quite an article in lake imports, and will hereafter pass freely towards tidewater for a market; but, as it is cleared at the canal office among sundries, we are unable to say what the quantity going east has been. The table below exhibits a full account of the canal business here for four seasons. Property shipped for tidewater;

	1842.	1843.	1844.	1845.
Flour—barrels	654,430	880,868	851,180	721,800

"While the deficit of flour is equivalent to 215,000 barrels, we find a prodigious increase of wool and other important items. A fraction less than 400 tons of the former commodity is observable over the shipment for last season. Cheese was 200 tons more, and flaxseed has increased 1,080 bushels; while clover and other seeds have fallen off 13,580 bushels. Tobacco has increased some, but not enough to meet the bulk of 1842-'43. Butter and lard combined have fallen off 21,500 pounds. The increased demand for lead here has absorbed all the import from the west. The increase in leather is very great, and much of the surplus going east is from manufactories along the lakes. Nearly all the hops required for consumption are imported from the interior of this State, or places along the seaboard. The few hides passing east are designed mostly for manufacture in this State. The perversion in the movement of dried fruit is singular. Large quantities were imported from below last season to supply the demand here and along the whole lake country. The increased shipment of staves shows a gain of 50 per cent.; but, as the cargoes leaving here are always estimated below the actual aggregate, the real increase must be still greater. Lumber can be more accurately measured, and shows an increase of 33 per cent. Nearly the whole of our best shipping lumber, such as cherry, black walnut, white wood, and cabinet and chair stuff, generally, are the product of this State, obtained from the two western counties bordering on the lake. The pine is all from Canada. A portion of the pine used for building here is from our own State and Pennsylvania. The vast increase in the quantity of coal going east cannot fail to attract attention, and was formerly adverted to as being entirely owing to the opening of the Erie Extension canal into the bituminous region of Pennsylvania. The diminution in the article of corn is of such magnitude as to call for the especial consideration of the canal board. With millions of bushels lying uncalled for in the Scioto and Wabash valleys, a tariff of tolls is pertinaciously adhered to which entirely prohibits its being brought northward, to increase our trade and augment the State revenues. Other coarse and bulky articles might also be particularized, but the above catalogue embraces so many that it were loss of time in attempting a detail."

"From the Albany Citizen.

Flour—wheat—barley.—The closing of the canal enables us to lay before our readers the quantity, as near as we can estimate it, of the above articles, which have reached tidewater this season, with the estimated value of each article.

Flour.—We have estimated the value of the flour at $5 50 per barrel for the year 1845, which is probably a fair average for that article in New York. The estimated value in 1844 was $4 50 per barrel.

	Receipts.	Value.
1845 - - - - -	2,482,527 barrels,	$13,653,898
1844 - - - - -	2,222,204 do.	9,999,918
Increase - - -	260,323	$3,653,980

Wheat.—We have estimated the value of this article in New York at $1 25 per bushel for the year 1845. The estimated value in 1844 was 96 cents per bushel.

	Receipts.		Value.
1845 - - - -	1,604,112	bushels,	$2,005,140
1844 - - - -	1,262,249	do.	1,211,759
Increase - - -	341,863		$793,381

Reducing the wheat to flour at the rate of five bushels to the barrel, we have the following aggregates, in quantity and value, of these two important articles in breadstuffs:

	Receipts.		Value.
1845 - - - -	2,803,349	barrels,	$15,418,419
1844 - - - -	2,474,654	do.	11,135,943
Increase - - -	328,695		$4,282,943

Barley.—We have more difficulty in averaging the value of this article than of the other two. We have, however, placed it at 59 cents per bushel for both sorts, and taken the average from September 1st to the present time. The average of last year was 63 cents per bushel.

	Receipts.		Value.
1845 - - - -	1,144,114	bushels,	$675,027
1844 - - - -	818,472	do.	527,410
Increase - - -	325,642		$147,617

It should be borne in mind that the above receipts of barley are the reported receipts of bushels, as appear by the clearances at the collector's office. Each boat, however, probably measures out, on an average, 200 bushels more than appear on the clearance. Estimating accordingly, the actual receipts this year at tidewater would be about 1,232,114 bushels, and last year about 881,472 bushels. This would make the increase in bushels this year over last, 351,642, and in value $159,847.

The Telegraph, after stating that St. Louis exports 12,000,000 pounds of bacon and pork annually, claims that Alton exported last year nearly 5,000,000."

A considerable amount of western produce has doubtless been sent to Canada during the past season. According to the table of imperial duties on imports into Canada, with the added colonial duty, some of our products would have to pay the following duties:

	Imperial duty.	Colonial duty.	Total duty.	
Flour and wheat - -	2*s.* per barrel,	0*s.* 6*d.*	2*s.* 6*d.*	per barrel.
Other flour and meal -	free	2*s.*	2*s.*	
Barley, buckwheat, maize -	free	3*s.*	3*s.*	
Rye, beans, peas - -	_	_	3*s.*	per qr.
Hay, per ton - -	free	_	6*s.*	per ton.
Bacon, per cwt. - -	3*s.*	5*s.*	8*s.*	per cwt.
Butter - - -	8*s.*	2*s.*	10*s.*	per cwt.
Lard - - -	4*s.* per cwt.			
Cheese - - -	5*s.*	2*s.* 6*d.*	7*s.* 6*d.*	per cwt.
Hams - - -	3*s.*	5*s.*	8*s.*	per cwt.
Meats, salted or cured -	3*s.*	2*s.*	5*s.*	per cwt.

A table comprising other articles may be found in appendix No. 31.

The Canada crops, with the exception of hay, spring wheat, and in some parts potatoes, were all good. "The schedule of tolls to be levied on the Welland canal during the coming season, (1845,) has been published. Flour, per barrel, 5*d.* currency. Pork and beef, per barrel, 7½*d.* ditto. Wheat, Indian corn, barley, and rye, per bushel, 1⅓*d.* ditto."

As regards our foreign market, it is well known that the crops of grain and potatoes on the Continent and in England are short; and we are daily in expectation of the modification of the corn laws, if not of the opening of the ports. The ports have been opened in Belgium, and as regards some articles which before paid duty in some of the West India islands. A large quantity of flour, wheat, and other produce has gone to England. The circulars of Messrs. Fitzpatrick & Henry, in appendix No. 32, will show the prices and give other information as to the state of the market for our products. The following is published in one of the public journals, as showing the amount of our exports from the port of New York, compiled from the New York shipping and commercial list:

Statement of the exports from the port of New York, for the years 1843, 1844, and 1845:

	1843.	1844.	1845.
Apples, barrels	15,015	13,463	14,439
Ashes, pot, barrels	43,046	40,532	46,724

In appendix No. 32 will be found a variety of papers in relation to the foreign trade, and British exports, &c.

The question is one of much interest to our country whether we may not succeed in introducing our corn meal (of maize) into foreign countries; and it is believed that with care in kiln-drying, the object may be effected. The experiments of Mr. Gill referred to in the last two reports, and in Mr. Ellsworth's letter in the present one, (appendix No. 1,) seem decisive. Let but the thing be fairly tried, and it is believed that it will be highly esteemed abroad. An interesting paper on the corn meal trade may be found in the appendix No. 32. It relates principally to the West Indies, but shows that there is an open market there for our enterprise. The subject of corn meal, &c., suggests to us here to turn the attention of our farmers and planters to the universal eccentric mill, a description of which will be found in appendix No. 33.

The opinion has been held that were the British ports opened for wheat and flour, or were our corn meal to find favor there, we should still be unable to realize any peculiar advantage, as other counties would be ready to pour in their supplies, (more favorably situated as to distance and the price of labor,) so that we should be unable for these reasons to compete with them. This remains, however, to be seen. It is believed that notwithstanding these apparent advantages, our enterprise would find means to introduce large quantities of our products into these ports. The price of labor is indeed much lower; but the unexampled fertility of our lands and the industry of our farmers, stimulated by the prospect of a large market, would leave a much more abundant surplus to dispose of than any other country could furnish. Some effort has been made to collect statistics as to the price of wages in our country, both of mechanical labor and that of husbandmen; and so far as obtained, the statement will be found subjoined in appendix No. 34. It is stated that in the course of the past year some seizures of American cheese have taken place, owing to their being marked with the brands "English Dairy" and "Cheshire Cheese." The handling of cheese is said to be extremely rough at the English custom-houses; the boxes are broken open, each cheese is examined separately, and then tossed without care upon the ground, and often into the dirt; so that a writer in one of the agricultural journals says many fine cheeses are thus often ruined by the treatment they have to undergo. Any attempt to counterfeit English brands must have a tendency to render these evils still greater, as they are almost sure to be discovered by the methods which are adopted. The objection to

some of the articles exported from this country, from insufficient packing, &c., has in a degree been obviated. Considerable pains have been taken by extensive houses at the west; and we have seen it stated in one of the English agricultural journals that for this purpose packers, &c., have been sent out from Great Britain, well acquainted with all their most acceptable modes of preparing articles for the market. In addition to directions which have been heretofore given as to curing hams or bacon, we will subjoin one or two recipes which we have met with in established English journals. The following is from the London Agricultural Gazette, which is published with the Gardeners' Chronicle. The writer states that he has been accustomed to cure bacon for home consumption for many years. His directions are as follows: "As soon as the flitches are cut from the hog, lay them on a form or table in a slanting position; and, supposing the whole hog to have weighed 12 or 14 stone, take one-fourth pound of saltpetre, pounded very fine, and sprinkle it all over the flitches, rubbing it well into the shoulder parts especially; let them remain 12 hours, when they should be rubbed dry; and in the meantime mix seven pounds of salt with one and a quarter pound of coarse brown sugar, stiring it well, that it may all be of the same temperature. The mixture, as hot as the hand can possibly bear it, is now rubbed well into the flitches, which are put one upon the other, and laid into a salting pan or other contrivance, in order that the brine may form and be kept from waste. The bacon must be kept in this situation four weeks, turning it and basting it well with brine twice or thrice a week. At the expiration of this time take the bacon from the brine, hang it up to dry, and smoke it if preferred, which, in the absence of a regular smoke-house, may be done as follows: Hang up the bacon in a chimney or other orifice, then underneath put down a layer of dry straw; upon this a layer of mixed shavings, keeping out those from deal or fir; next a good layer of sawdust and some juniper-berries, or branches where procurable; and over all a mantle of wet straw or litter, which makes the fire give out much smoke, without burning away too rapidly. This smoking must be repeated three or four times, or until the bacon appears thoroughly dry, when it may be hung up in the kitchen or any dry place convenient."

A correspondent of the same paper gives the Yorkshire method. He says that after being killed, he allows it to hang 24 hours previous to its being cut up. He then rubs one pound of saltpetre on a pig 20 stone in weight, and with this 20 or 30 pounds of common salt, taking care to rub it well in; then it is laid in a tub kept for the purpose. After it has laid for a fortnight, it is turned over, and a little more salt (say 3½ pounds) applied; it then remains a fortnight longer in the pickle tub; it is then taken and hung up for two months in the kitchen to dry, unless winter is far advanced and dry weather set in, in which case a shorter period will answer. After being taken from the top of the kitchen the inside is washed over with quick-lime and water, to preserve it from the fly; it is then removed into a room not used, away from heat, and where it may be kept perfectly dry. The plan is, not to smoke at all; the salt and saltpetre must be of the best quality.

The Hampshire mode is thus described: "Let the hog be killed only in the morning, in a dry day, and when the wind is from the north, it having fasted the day before. Hang it up, when dressed, in some airy place for twenty-four hours, and then cut it up. Lay the flitches on the ground, and sprinkle them lightly with salt, and let them lie for six or eight hours;

then turn them up edgeways, and let the brine drain off. Take two or three gallons of the best salt and two ounces of saltpetre, pound them fine and mix them well together, and, on a salting bench of the best seasoned oak, salt them by rubbing in the salt on the backside of the flitch. Then turn the inside upwards, and lay on the salt about one quarter of an inch thick. Neither rubbing nor saltpetre should be used again, or it would make the lean bacon hard. Change and salt them every third day for six times, when the bacon will be salt enough. Then rub off all the stale, briny salt, and lay on each flitch a covering of clean, fresh bran or sawdust, and take it to the drying-loft. It should be hung there by means of crooks in the neck of the flitch, and remain for fourteen days. He recommends, for drying, cleft oak or ash."

The following is given in Costello's Tour, as the method of preparing the celebrated *jambon de Bastogne*, or Ardennes ham, which is pronounced by the tourist to be an incomparable dish for the epicure: "The ham is cured in a brine of salt, saltpetre, and aromatic herbs, viz: a few bay leaves, wild thyme, and a handful of juniper-berries and a little garlic. It is steeped for about six weeks, and then dried in the smoke of the chimney over a wood fire. When wanted for dressing, it is buried in the ground for twenty-four hours, and then boiled, with the addition of the same aromatic herbs in the water. After boiling, the bone is taken out, and the ham is pressed under a heavy weight. As a corollary to the dressing, it is added that the ham, when produced at table, disappears at one sitting."—*Mark Lane Express.*

Other methods of curing hams and beef, &c., will be found in appendix No. 35.

In the January number of the American Agriculturist, (1846.) we find an interesting account of an invention by Mr. Davison, for curing provisions, which promises to be of much advantage in many cases. The statement has so much engaged our attention, that we have transferred it to an appendix, (No. 35.) "The principle on which the method acts is that of a pressure upon the meat in a vacuum." The advantage is *rapid* curing. It may be done in twelve hours ready to pack, which is a great gain of time, storage, &c.; its juices will not be lost in brine; it may be cured in summer as well as winter. Thus less capital will be required at the west for the purchase of meat, as time, interest, storage, and insurance are saved. They can also begin to pack earlier. Meat that is skippered or tainted, it is said, can be saved and restored. Old hams and bacon that will not take pickle by immersion, by the vacuum process may be made to do so; meat *warm* may also be cured and packed at once; it can be made to keep in warm weather, &c. Another application of the method, it is said, may be made to impregnate wood, &c., with salt. The apparatus employed, it is likewise stated, is an extremely simple and economical one. It is not improbable that our articles of provisions have, in many instances, suffered in foreign markets, owing to the poorness of the salt with which they are prepared. Much of the salt made in this country, and also the Liverpool salt, contains impurities which injure its fitness for the purpose of complete preservation. It is not to be doubted that what is prepared by the solar process, or which is called the solar salt, may be fully equal to any other; but it is said that this bears a small proportion to the whole manufactured. The analyses that have been published show a wide difference in regard to saline qualities in this kind of domestic and other descriptions of home

manufacture. Now it is well known that butter requires the best of salt, and it is often injured by want of care in that respect. The committee of Addison county, Vermont, in their remarks, say that none but the best Turk's Island (not even Liverpool blown salt) will answer for this important purpose. The same objection lies against many of our salts as to using them for curing pork, beef, &c. The longer there is want of care or attention on this subject, the longer will our provisions be subject to depreciation abroad. The best economy, therefore, is undoubtedly to use the best article, as this will insure the best prices.

We have thus taken as full view of the crops as in our power, with the means at our command, adding also various other kindred subjects, as seemed appropriate. Many may, no doubt, dissent from some of the estimates we have made, and will believe that they can form conjectures nearer the truth. We do not deny such a possibility, and shall not attempt any dispute with their fancied superiority. If more correct, we shall be glad that our countrymen may be benefited by their deductions. What has been attempted and done has been in all honesty of purpose, and in the hope that our farmers and planters will not esteem the effort altogether fruitless. But before we close, we trust it may not be unfitting to look for a moment or two at some considerations bearing on our future agricultural prospects.

FUTURE AGRICULTURAL IMPROVEMENT.

There are some things which seem to authorize our augury of still greater advances in agricultural improvement. And in touching on these, we shall, at the same time, suggest the points of deficiency which still remain to be supplied.

The first ground of encouragement on which we rely, then, is, *increasing agricultural knowledge.* To any one who will take the pains to examine the list of agricultural periodicals, and compare it with that which would comprehend all the weekly or monthly journals of this description a few years since, the contrast will appear striking. Nor is it only in the number of these, and the wider extent of publication and circulation which is enjoyed by them, that this difference is manifest. They are not merely printed in more sections of our country, but they are much superior in their appearance and their contents; to say nothing of the beautiful and highly finished illustrations which make a part of them. Instead of being confined to results at home, they are filled with letters from able correspondents abroad, as well as condensed views and extracts from foreign works of high reputation. We have thought it might not be an uninteresting addition to our appendix to subjoin a list of our agricultural periodicals, and such will accordingly be found in appendix No. 36. These weeklies and monthlies having more or less extended circulation, exert a very important influence on the public mind, and thus a direction has been given to the public feeling. The effect of this, and the impulse which has been given, are seen in the various channels which are every where open to meet the craving for greater supply. The editors of many of our public journals have discovered that mere political intelligence, or scraps of literary intelligence and wit, are not all that are demanded from them by the yeomanry of our country. There must be an agricultural department, or a column, at least, devoted to agriculture, to secure the patronage of the farmer subscriber; and, accordingly, there are not a few of our political journals which

weekly furnish articles, selected or original, on subjects connected with this great branch of American industry.

Another means of diffusing such knowledge, is the publication of volumes of standard merit relating to agriculture. We think it truly an auspicious era in our country, when such works as Thaer's, Liebig's, Johnston's, Mulder's, Petzholdt's, Youatt's, Dana's, and many more—too long a list to name here—are brought within the reach of our agriculturists. If they do not at once give up former views, and adopt those which accord both with science and experiment, yet we can hardly doubt that in many cases these will exert a modifying influence on their practice. Gradually they may be led to feel the importance of such things, and another generation, if not the present, will be found to be imbued with correct principles of agricultural science.

The brilliant success which has attended recent demonstrations on the part of the well-trained and thoroughly disciplined minds who led the way in the reformation of agricultural chemistry and vegetable and animal physiology in their applications to practical use, has prompted new aspirants to fit themselves thoroughly to share in the nicer discriminations and new discoveries yet to be made.

We hail it as a cheering promise in this respect, that there are minds of enlarged views and accurate investigation abroad among us, and operating on the most intelligent of our agricultural population. These authors, whether of our own or of other countries, are only the precursors of a constantly increasing agricultural literature, which is destined to render more efficient the means at our command for covering our land with smiling fields and waving harvests, so that literally the wilderness may yet "bud and blossom as the rose." The increased training of the youthful mind agriculturally, is also another feature which augurs well for us. We refer here to elementary treatises adapted to the young, to the establishment of agricultural schools, and to the proposed introduction, in a degree, of some of these topics in our common schools. There is much not merely to expand and invigorate, but also to interest the mind, in agriculture, studied in its bearings on various sciences. Chemistry, with its beautiful illustrations of combination or decomposition; geology, with its marvellous and time worn relics of past ages; entomology, and its curious developments; together with the mysteries of animal economy, vegetable physiology or botany—all are made to open their treasures and present their attractive claims. The young student is brought thus to a world of wonders; and his attention once arrested, he cannot but find that agricultural study, in the broad view which should be taken of its domain, has sufficient to amuse and to discipline the faculties of intellect and heart. Its influence can scarcely fail to be salutary, as it leads him to the great laboratory of nature, and shows him how the operations of Providence keep at work the means of supply, and that decay is only succeeded by reproduction in some other form of vegetable life. It is scarcely necessary to say that, with these inspirations of science, he will be the promoter and patron of improvement in every shape, and that he will be foremost in upholding the agricultural club, the county or State association, with its fairs for exhibition of products of industry. These, too, the more they are multiplied, will exert a wider influence. Our countrymen are apt to observe and to invent; but they need more precision and discipline in the development of their operations. As these are acquired by a severe training in science, the results

will be seen in a thousand ways. We point to one desirable improvement which, if it were accomplished, would doubtless exercise no little influence on our agricultural prospects. We refer to the adoption of some such course as is taken in the great agricultural meetings in various countries of Europe, where a week is spent by persons brought from all parts in discussing subjects of agriculture, previously arranged in a printed programme. Some idea of what we mean may be gathered from the perusal of Mr. Fleischmann's letter, and also the translation of the regulations relating to the great agricultural meeting at Breslau last summer. (See appendix No. 37.) It is true that something of the same kind on a small scale has been attempted at Albany, Boston, New York, and other places, during the sitting of the State legislature, or weekly, and we see not why the object might not be attempted and executed successfully on a much larger scale in our own country. A paper on subjects of discussion, with reference to works on agriculture, which we have taken from the London Gardeners' Chronicle, will be found in appendix No. 37.

Another ground on which we rest our augury of prospective improvement in this great branch of national industry is *the application, in new forms of enterprise, of the products of the soil, and of the departments of collateral husbandry.* To take a single instance for illustration. It is but a few years since the improvements were introduced by which such quantities of lard and lard oil are prepared for the market. The business connected with this has already run out into varied channels, and so it must be with every new invention which appropriates the fruits of the farmer's toil. One branch of labor gives rise to yet another. But our career in this respect seems but just begun. The vast increase of inventions, the numerous shapes through which industry is developed, all furnish reason to believe that we have by no means reached the end of our progress. The enlargement of these outlets of skill and enterprise, and the prospect of increased civilization through our commerce abroad, will undoubtedly have a tendency to make our land teem with an industrious population, whose wants will multiply as their wealth shall increase; and thus, through the diversified reciprocities of trade at home and abroad, a more steady and reliable market be created, which shall help to enrich the diligent and reward the efforts of successful economy. It will not be long, as we confidently believe, before an average uniform price at points equidistant from the great marts of commerce will be established throughout our land by means of telegraphic communication, and the facilities of conveyance be so multiplied as to check the inequalities induced by speculation, and give assurance that they who provide by the sweat of their brow for an extending empire of freedom, shall not labor in vain. If affluence may not be the lot of all, yet steady prices, on which they may count, will aid the contented and industrious spirit to enjoy the comforts and many of the luxuries of life, of which others in the same employment and occupation in foreign countries are so greatly in need. (Charcoal roads are suggested as valuable in some of the States. See appendix No. 38.)

From considerations like these, (and others, too, might be mentioned,) if we are not mistaken, there is ground for cheering augury of agricultural improvement, which, though its progress may be gradual, will yet be certain and permanent, as well as productive of happy effects on our country and the world. That there is a rising feeling in favor of agriculture, the ten thousand voices echoing back from every quarter to us, in approbation

of the humble efforts made from year to year in collecting, and, through their own representatives, laying before our farmers and planters the information of various kinds within our reach, abundantly testifies. We might, likewise, refer to the embodiment of this feeling in resolutions at the farmers' convention, (see account of this meeting, appendix No. 39,) urging the importance of their claims to regard, and as it meets us stronger and stronger from year to year in the agricultural journals in all parts of the country. Never was there a fairer time to aid its development. Without resorting to more questionable means, which might rather injure than benefit, it lies in the power of those who occupy places of influence to lend a warm-hearted co-operation to every effort of improvement, and to diffuse as much as possible a generous spirit of enterprise into all the branches of agricultural industry. We indulge, we are sure, in no fancied dreams when we say that the past years have only been the harbinger of a more perfect agricultural economy. It is with presages like these, while we see our bounds enlarged, we watch every indication of the awakening of the mind of our country to the importance of true science and practical knowledge. It is matter of gratulation to learn that a new agricultural journal has made its appearance, like a star first breaking through the darkness, in any section of our land which, till recently, could furnish no such proof of advancing knowledge. The information that a successful experiment, too, has added another name to the list of our products, or that the introduction of some choice specimen, either animal or vegetable, has brought to the agriculturists of those States the means of yet greater progress in improvement, is read with the confident expectation that another impulse has been given to the energies of industry, the results of which after ages will record with grateful satisfaction. Compared to the whole, each individual enterprise is but as a pebble dropped into the wide waters; but as even that slight motion agitates the nearest surface, and one wave after another spreads silently on, yet further and further from the place where it begun; so the community, in increasing circles, will feel the effect of every such event. One and another will follow on—a township, a county, a State, and yet larger portions of our country will in turn welcome the stranger, till it shall have made itself a home, and become domesticated and acclimated among our products.

Esto perpetua! is the prayer of every patriot as he casts his eye over our land of varied clime, and soil, and product, and people. With no stinted hand have the gifts of a kind Providence been strewn around us. The earth and its increase—flowers, fruits, animal, bee, worm, and fowl—all bear their tribute to supply our wants; and so profuse are the means of sustenance and comfort, that every year, almost, only serves to lap us in greater plenty. It is to agriculture—

> "The art that calls the harvests forth,
> And feeds expectant nations"—

we must look as the oldest employment, and the most necessary occupation of man. Honored, it will make our country glorious in the true strength of a nation—its virtue, intelligence, and enterprise. Neglected, the arm of prosperity will be shattered, and our experiment may end in doubt and dismay.

APPENDIX.

No. 1.

Letter from the Hon. H. L. Ellsworth.

WASHINGTON CITY, *January* 1, 1846.

DEAR SIR: Since my resignation of the office of Commissioner of Patents, I have availed myself of the opportunity to revise some of the estimates of my former report, especially those of the population of the United States. Though one of the data I had for my guide was the census published by government, a comparative increase, as exhibited by the ratio of the last ten years previous, was the basis of the population given. Several of the States, however, have lately taken an enumeration of their respective inhabitants, and thus afforded safer data in part. A personal revision of the computation, directed while in office, and which I had not time to examine, has also enabled me to correct important errors; and I have now to request that you will publish in your forthcoming report the estimates which I have, with no little labor and correspondence, prepared. Since my connexion with the office terminated, I have prosecuted several inquiries, principally on agricultural subjects, commenced soon after the transmission of my last report to Congress. The result may, perhaps, interest those who have expressed an approbation of the agricultural statistics emanating from the Patent Office. I have, too, had an opportunity to reduce some of my theories to practice, and it may be gratifying to hear of my success. Together, therefore, with a corrected estimate of the population of the United States, I submit an improved method of cultivating the prairie lands, in the hope that government will thus be benefited in making sales of territory now deemed of comparatively little value, on account of the scarcity of timber, and that individuals may be encouraged to make improvements to better advantage. Other matters, also, are subjoined, viz: an account of an improved method of preparing flour and Indian meal for exportation or for private use, whenever it is an object to guard against the evils of fermentation; the particular directions as to the preparation of hemp for market, (with the comparative value and expense,) as practised by Mr. Billings, and transmitted by him to me at Lafayette; the suggestions of Mr. E. G. Kelly on the subject of bees—more important as coming from a practical man—showing how to obtain pure honey, to produce artificial swarms, prevent robbing and the ravages of the moth; directions for the construction of hotbeds, offering a substitute of canvass for glass, a desideratum both in economy and greater benefit to plants; (and having examined some beds lately constructed, I consider the improvement important.) In former reports the culture of mustard was recommended, and the successful efforts of Mr. Parmalee, of Ohio, mentioned. It has not been until lately that I have been able to obtain from that gentleman those particulars which I desired. I am now able to transmit to you the most full information on the subject, and do not hesitate to recommend this crop whenever

labor can be found for thorough cultivation. There is another subject highly interesting to the citizens of the United States—the supply of oil for burning. The great leviathans of the deep are fast disappearing, and are even now found most successfully amidst the ice near the poles. An interruption of commerce may prevent this traffic. Napoleon, who was so pre-eminently careful in providing for the contingencies of war, spared no efforts to obtain a substitute for oil from the sea, and encouraged the culture of rape, colza, and other oleagenous seeds. It is worthy of remark, that, at the present time, the light-houses and other public works in France are lighted by the oil obtained from colza; and it is found that this oil is the best substitute for sperm oil, being so pure as to burn well in the most improved French lamps. Through the kindness of Mr. J. W. P. Lewis, civil engineer, so favorably known for his thorough investigation of the subject of lighting the coast and the harbors, I have been able to obtain from France seed of both the summer and winter colza, which I have the pleasure to place at your disposal, accompanied by a translation, by the same scientific gentleman, of the mode of its culture and manufacture, from a work by a distinguished scholar and philanthropist, M. Hotton. Although now separated from the bureau so long intrusted to my superintendence, be assured my desire for its prosperity has not diminished, and I ardently desire and hope that you may find in Congress a continued willingness to provide the means of extending its greater usefulness under your administration.

Yours, very respectfully,

HENRY L. ELLSWORTH.

Hon. EDMUND BURKE,
Commissioner of Patents.

An estimate of the population of the United States—January, 1846.

Maine	575,500
New Hampshire	291,500
Massachusetts	817,000
Rhode Island	120,000
Connecticut	320,000
Vermont	298,000
New York	2,626,000
New Jersey	409,000
Pennsylvania	1,960,000
Delaware	79,000
Maryland	485,500
Virginia	1,255,000
North Carolina	760,000
South Carolina	600,000
Georgia	784,000
Alabama	660,000
Mississippi	586,000
Louisiana	440,000
Tennessee	910,000
Kentucky	835,000
Ohio	1,760,000

Indiana	860,000
Illinois	722,000
Missouri	540,000
Arkansas	140,000
Michigan	320,000
Florida	80,000
Wisconsin	100,000
Iowa	115,000
Texas	100,000
District of Columbia	54,000
	19,602,500

CULTIVATION OF PRAIRIE LAND, &c.

The vast amount of prairie land owned by the United States, although rich and fertile, remains still uncultivated, and will continue so until the expense of fencing is reduced. Some persons that have entered this kind of land already meet great embarrassments; while others, that have adopted the modern improvements, rejoice that they have escaped the toil and expense of clearing off timber, when the land was covered with wood. In my former reports, as Commissioner of Patents, I have frequently alluded to this subject, and offered many suggestions for the consideration of others. Since leaving the Patent Office, I have been enabled to reduce my theory to practice, and will give you a detail of operations which have proved successful. In *breaking up the prairie*, five good yoke of cattle are necessary, if the large breaking plough is used. This team may be composed of two yoke of old well-broken cattle, and three yoke of unbroken steers, and will break from $1\frac{1}{2}$ to $2\frac{1}{4}$ acres per day, according to the weather. It may seem surprising that only one man or boy is necessary, viz: a driver for each team. No person holds the plough. I have had seven ploughs at work during much of the summer, and the plough, as is said, "holds itself." This novel sight attracted the attention of travellers, who often alighted to see how the work was performed. The arrangement to effect this was simple. Two small wheels, made of plank, with a short axle, were placed in front at the extremity of the beam, which was fastened so as to keep the plough erect, to govern the depth of the furrow, as well as the width of the same. Sometimes both wheels are made to run upon the turf; it is better, however, to make the wheel of the furrow about 8 inches in diameter, the largest; (this will keep the axle sufficiently level.) The seven teams, which were driven by youths 14 to 16 years old, required one judicious man to keep the ploughs in order, for sometimes they would come in contact with stones, and roots, almost as bad; and, in all cases, the ploughs often need sharpening, which is done by either hammering or filing the share. The usual price for breaking up prairie land, near my residence, is $1 50 per acre. This work can be done much cheaper, however, by hiring a man at $18 per month, or $16, he boarding himself; since the team is supported on the prairie, and there is little extra expense, except the repairing of the plough. Another mode has lately been adopted in breaking up the prairie, viz: with a single span of horses. To accomplish this, a coulter, with a

share six to eight inches wide, is first passed through the sod; this, it is perceived, must cut vertically, and also horizontally, as far as is necessary, it being desirable not to cut the whole distance of the furrow, since the remaining operation requires a part of the sod nearest the furrow to remain solid. The second operation is the running of a common plough, with a sharp share, (with or without a coulter,) in the same track. The only obstacle to its easy passage is the outer edge of the furrow of a few inches; this is cut or broken, and the furrow easily turned over. This plough will enable a settler, if the land is ploughed in the spring, being then much less compact, to break up, with his span of horses, $1\frac{1}{2}$ acre per day.

There has been much diversity of opinion as to the depth of the furrow, and the proper time of breaking up. From three and a half to four inches is sufficiently deep; the turf sooner decomposes if it is cut shallow rather than deep; then the lower roots decay rapidly, and in a few months the tough rigid soil, that requires five yoke of cattle to break it, is easily ploughed six to seven inches deep with a pair of horses. As to the first time of breaking, if the sod has been tramped, blue grass springs up, and the roots of original sward begin to perish, and it is of less consequence when such sod is broken. As respects original tough prairie sod, this should not be ploughed until the grass has fairly started, say in May or June, and July; if broken up much earlier than May or later than July, the sod does not decay so soon. It is usual throughout the west to break up the sod during these months, and sometimes even later; and in September and October to harrow in the wheat for the first crop. Another mode I have, in common with some others, pursued with great success, viz: to raise a "sod crop." This process to eastern farmers needs explanation. In every third or fourth furrow corn is dropped at the outer side of the furrow, computing from the land side. This is buried up by the succeeding furrow, and the corn springs up through the partial crevice; and if perchance the sod lies flat upon the corn, it will generally in its growth force its way through the solid turf, strange as it may seem. The land thus ploughed is remarkably free from weeds, and the corn in ordinary seasons grows rapidly. No hoeing is needed, and nothing is done to the crops until the time of gathering arrives, when often from thirty to sixty bushels of good corn is obtained. The cost of dropping the corn is ten cents per acre; one small boy attends three ploughs. My sod crop this year was not so great as that of some of my neighbors, who chose a more propitious moment for planting. From one hundred acres, however, I estimate my crops at an average of thirty bushels of shelled corn per acre; some raised as high as sixty bushels of sod corn, being the full amount of the yield of corn commonly tilled on good soil. My friends from the east were greatly surprised at finding a crop of three thousand bushels of corn from one hundred acres of land, without tillage. This sod crop may be considered almost clear gain, since the shade afforded by the growing corn is rather beneficial than injurious to the decay of the sod for a wheat crop in the fall. For if the sod crop is put in early, it can be cut off in the fall in sufficient time to harrow in a crop of wheat; this is done without any further ploughing, and gives generally the largest and best wheat crop raised on the land. It is thus seen how easily a settler can supply himself with food for his family in a new home at the west. While passing through the fields near my own, I was struck with the culture of beans planted in the same manner as sod corn; and these grew also without any subsequent cultivation, and yielded a good

crop. Nor was my attention less arrested by a crop of corn and beans growing together, the stalks of corn serving as poles; all were planted together in common ground. The extraordinary product induced me to inquire for the owner of the field, and I found him to be an intelligent farmer, Mr. McAllister, who said he had tried the same thing with like success before, with no hoeing, barely ploughing. He thought he should get eighty bushels of corn and thirty bushels of beans per acre. I requested him to measure the ground and the crop, and give me the result in the fall. He did so, and his certificate, to which he is ready to make oath, is now on file in my office. His product, by his statement, was one hundred bushels of shelled corn and fifty bushels of beans per acre! From the small quantity of land measured, and the most favorable manner of enclosing within his lines the hills of corn, I have made a liberal allowance, and place the crop with certainty at eighty bushels of corn and thirty-five bushels of beans per acre; and all this without hoeing or any other culture than the passing the plough or harrow three or four times between the rows. It may appear to be rather slovenly to omit hoeing, but such is the practice. On one of my plantations, in which are one thousand acres in cultivation, I have not seen a hoe used during the summer. I think more care and attention would be rewarded; still the land yields upon an average fifty bushels per acre, annually, without hoeing or manure. I was offered sixteen bushels of corn as rent, per acre, instead of one-third of the crop, which is the usual share for the landlord. I preferred, however, the one-third, and got twenty bushels; the season being very favorable, and the land yielding sixty bushels and some as high as eighty bushels per acre; fifty bushels, however, is a good crop; and when the hazards of the season are considered, sixteen bushels per acre may be called a good rent. With this conviction I have rented one thousand acres of ground for sixteen thousand bushels of shelled corn delivered in the crib.

While corn is so easily raised, it may be asked, what is its value? At present, the price at Lafayette is about 20 to 25 cents for exportation to New York *via* the lakes, the Wabash and Erie canal, or to New Orleans *via* the Wabash, Ohio, and Mississippi rivers. Considerable shipments are also made to Canada. It is hoped that the State of New York will further reduce the tolls on her canal so as to insure an outlet for the corn and oats raised in the western States. At present these articles of produce are not shipped through that channel. If the tolls were reduced, a larger traffic (which would be clear gain to the canal) would be obtained, and also full freight for the boats in the "slack season." If the corn is fed out to cattle or hogs, (for beef and pork,) at present prices it is worth from 20 to 25 cts. per bushel. In the mode of feeding corn there is a diversity of practice; some graziers turn both cattle and hogs into the field of corn, to consume what they wish. Care must be taken, with regard to cattle, by letting them remain only a short time each day, at first. The fat cattle and fat hogs are first admitted, and follow each other; next the store cattle and store hogs. Nor is there so much loss sustained unless the weather is very wet, as might be supposed. Hogs will not pull down corn faster than they wish to eat it. Cattle do more injury; yet the hungry hogs will glean up most that falls on the ground. Both cattle and hogs consume, also, much of the succulent stalk, and the operation of this mode of feeding enriches, as may be supposed, the soil for a succeeding crop. I have serious doubts which is the most advisable mode: whether to cut up the corn and feed it to stock in pens,

or to let them consume it on the hill where it grows. Much will depend upon the division fences, the size of the field, and the advantage of water. Where these are adventitious, and labor not plenty, it is best to turn in stock, especially hogs. The usual mode, however, is to cut up the corn, stack it, and feed it out. This is necessary for stall-feeding, in winter, in order to save the fodder, so greatly injured by the frost. I have been able to hire land, tilled with a corn crop, at $2 50 to $3 per acre; the average yield being 50 bushels. The cost per bushel, standing in the field, is about 5 to 6 cents only, exclusive of the rent of the land. Several farmers have fattened the past summer as many as 1,500 hogs, and made most excellent pork. One and two hundred are considered an ordinary number. Hogs are usually killed at about 18 months' old, and weigh from 200 to 300 lbs.; they are fed on clover during the summer, and are suffered to run in the woods; in winter, if the mast is favorable, they live in the timber; if not, they are fed with a few ears of corn each. A preferable mode is to keep them better, and kill them earlier; the pork is finer, and commands a higher price in foreign markets. At the east it is no uncommon thing for spring shoats to weigh, at Christmas, 300 lbs. Having noticed in the papers an account of an extraordinary pig, raised by Mr. Wm. Moore, of Peterborough, New Hampshire, and which weighed 622 lbs. at 10 months and 15 days' old, I wrote to ascertain the fact. They are given in his letter, marked AA. I intend trying an experiment with a hundred pigs, taking care to weigh the food they consume, feeding them with slop or cooked food, and will note the result. I have no hesitation in recommending the following method as safe and profitable, viz: Clover for the early part of summer; next, rye fields and oat fields, (if peas are sowed with oats, the better;) and the cornfield to close. If an early kind of corn should be planted to use first, it would be well. In all such cases the hogs are to be their own harvesters. This plan keeps up a vigorous growth, and prepares the hogs for an early market—two important considerations.

There is much encouragement for the western farmers, and the reduction on the tolls, occasioned by the competition on the same and different routes, will make the encouragement greater still. Pork, it will be admitted, is very easily raised. We are now enabled to contract for its delivery in barrels, via the canals, from Lafayette to New York, for $12 50 per ton, or five-eighths of a cent per pound. It may be asked if this rich soil will not soon be exhausted? It had been supposed that it must, but large fields have been cultivated this year, (being the sixteenth year in corn,) and yielded 50 bushels per acre. There is, however, a gradual diminution of the quantity, and hereafter the farmers will be willing to save manure, which is now thrown away. I was surprised to find hundreds of loads, carted at an expense of 12½ to 20 cents, and thrown into the river to get it out of the way. Such still continues to be the practice in Lafayette, where the population is upwards of 3,000.

The machine for husking and shelling corn, at the same time, deserves mention as a great auxiliary in preparing the crop for market. When propelled by any power equal to four horses, it will husk and shell five hundred bushels daily.

I might here mention a new kind of corn lately introduced, viz: the yellow Dent corn, the ear of which is very long, and the color preferred for meal and for shipment. Its yield has been 125 bushels per acre. I take pleasure in sending you two ears—one for the gallery, and one for

distribution. I shall give the same a full trial during the summer. The samples I obtained at Indianapolis.

I have mentioned in particular the corn crop. The wheat crop is, however, the crop for exportation; 500,000 bushels of wheat will be shipped from the late harvest about Lafayette. This crop has been unusually good the last year, and the yield from 15 to 25 bushels per acre. A remarkable circumstance occurred in my wheat field, where several varieties were sown. The red-chaft bald wheat was attacked by the army-worm, and the stalks completely stripped. When the worms reached the white flint wheat, obtained of Mr. Harmon, of Wheatfield, N. Y., *they stopped, and went around the piece without touching a single stalk!* The attack did not essentially injure the berry of the bald wheat, on account of the lateness in which it took place. Potatoes, also, were good, but the crop is not so great as usual. The disease so much complained of has not yet reached us, but I expect it along very soon. It seems to be commissioned to go through the world, and yet defies us to explain its origin or find a cure.

I cannot omit to mention the important results which have attended my former recommendation of salting cattle and hogs, with a composition of salt, ashes, and clay. You may recollect that I advised to take water saturated with salt and mix it with two parts of dry ashes and one part of dry clay, and when the whole was brought to the consistence of clay mortar, to mould it into a pyramid shape and suffer it to harden, and then put it into the field where stock could lick it at pleasure. This experiment has been fully tested, and herds together, hitherto afflicted with the bloody murrain, have been exempt from any further attack. The clay is not, I suppose, so material. Ashes and salt in equal quantities, mixed, if convenient, with bran, may be given to cattle, horses, sheep, and even hogs, once or even twice a week, with the most happy results. The solid cakes, however, allow the feeble stock to obtain their share; indeed, this plan gives to *all as much as they desire*, and *at the time* they desire it. Sheep will usually lick the cake every day.

In bringing the land into tame grass pasture, it is found necessary to scatter blue-grass seed, which, being tramped in, soon yields a great supply for summer and winter food; for if the cattle were taken off from the blue-grass pastures in May, and the field is left to grow up until fall, they will survive and keep in good order upon it during winter, without any other attention than salting; if the grass is covered with snow only, cattle will paw off the same until they reach the relished food. As for sheds, they are, as yet, unknown; no large feeder has them, to my knowledge, in Indiana. It is said that so much shed room is required, that it will not pay. Hence cattle are stuffed with corn, and remain in the open air during all kinds of weather. I am satisfied, however, that the time will soon come when shelter will be acknowledged to be a great saving. At present, farming is done upon a great and easy scale, and little, very little, attention is given to economy; and what is real economy in the present state of the fertile west, where land and stock are so plenty, is not quite certain. I will only add, on this point, that the cattle are pastured upon the unenclosed prairies during the summer and fall months, without any expense other than salting. On these pastures they are in fine condition for the shambles or for stall feeding. For the latter purpose, they are now taken to Ohio and Pennsylvania by graziers, who improve them, and drive them

to the eastern markets. Cattle direct from the prairie are now packed in great quantities for the European markets. Shipments during the past year have encouraged larger exports this year; and if the beef sent will not find admittance into England for home consumption, it will be received in bond, for supplies to ships outward bound.

You might have expected that I should have mentioned *fencing* land, before I gave you an account of its cultivation. The order is of little consequence, provided you have the substance. I cannot but hope and believe that my experience in fencing the prairies will be useful to individuals, and help the government to sell its vast tracts of land now lying waste because there is no timber to fence them. Happily, on many of the great prairies (such is the case in the section where I reside) bituminous coal of an excellent quality is found, sufficient for domestic use. Timber is scarce; and to practise economy in this respect, I have recommended and adopted the following plan with success: On the line for the fence, holes are dug or bored about 1 foot deep to receive the posts designed to hold the rails. The post is bored for three, four, or five rails, with a $2\frac{1}{2}$ inch auger, moved by a single horse power. Two contiguous holes give a mortise $2\frac{1}{2}$ by 5 inches. One man will bore the posts for one-half to three-fourths of a mile of fence per day. For a fence for cattle only 3 inches are used. For hogs a small rail is added at the bottom; but this is covered up to secure a barrier against the rooting of the hogs before the bank becomes solid. The rails, when set, are about 12 to 18 inches above the surface of the ground. This distance is filled by a plough and scraper, described in my reports while Commissioner of Patents. As this may fall into hands where these reports cannot be had, I will repeat that a large plough is passed on each side of the fence, turning the furrow towards it. This is followed by a very simple machine, made of two planks, resembling in general appearance a snow-plough, though in detail constructed differently. The land side which follows after the plough (by another team) is, say 15 feet long, 3 inches thick, and a mould board 15 inches wide is attached to this about 2 feet from the front, at an angle of 21 degrees, the angle being such that the dirt will not stick to the mould board—different soils admitting different degrees. The sides of the mould board and the land side are shod with a strip of iron, extending $1\frac{1}{2}$ to 2 inches below the bottom. This is to make the machine enter the ground easily, and to cut the turf if necessary when lying loose. This angle can be increased or diminished by making the mould-board to move on a hinge, which is best affixed about 2 or 3 feet from the front end of the land side. As the plough which precedes will cut about 6 inches deep each time, 3 or 4 furrows may be found to be sufficient. The machine follows, and throws up the dirt, making a handsome bank on each side of the fence of such a slope as may be desired. The bank is raised 18 inches above, and the ditch cut 18 inches below the surface of the ground, thus giving a height, both included, of 3 feet. This bank helps to sustain the fence, and, leaving a ditch on either side, checks cattle from jumping; for whoever has watched the movements of stock soon discovers their great aversion to jump *from* a ditch *into* a ditch. Grass seed is sown upon the sides of the ditch, and they soon become solid. These ditches serve to drain the soil when it is wet, and also, when water is scarce, as a conduit for the rain to an artificial pool, which, by excavation, can easily be made, and covering the bottom with clay where the soil is sandy. The saving in this kind of fence is most mani-

fest. There are about 520 panels to a mile. Three rails would require 1,560; four rails, 2,080. These need not be more than $2\frac{1}{2}$ inches thick, but wider than the common narrow rail. A common Virginia or worm fence requires about 8 rails, besides stakes and a rider, to each panel; and four panels of a zigzag fence extend no further than three panels of the straight fence. Four panels of the crooked fence require 40 rails; thus there is a saving of 28 to 31 rails in this distance. In a mile the difference is between 1,500 or 2,000 and 6,000, a very important saving. If the rails are dry, the expense of carting 1,500 to 2,000, which make a mile of fence, is very trifling—only 15 to 20 loads. Besides all this, the Virginia fence leaves notches in the angles which cannot be cultivated, and serve as nurseries for weeds to poison the soil, and furnish fuel to consume the fence if exposed to fire. The same machine spoken of above is highly useful in turnpiking roads, because one of them will do the work of a large number of hands. Some bitter feelings had been engendered because I had interfered with those whose constant employment is to ditch with the spade. I might have mentioned that if twigs of cotton-wood or sycamore are inserted in the bank in the early part of the spring, they will take root and soon furnish shade and living posts. But locust seed, well scalded with boiling water, and suffered to lie in the same till cool, and sowed broadcast in mellow soil, will soon furnish most excellent timber, as well for posts and rails as for shade. The growth of the locust is astonishing. With these helps, therefore, we may expect a more speedy cultivation of prairies. Even now some large landholders have quit their timber lands and gone far into the prairies, where the land is ready for the plough, and thus avoided the expense of 10 to 12 dollars in clearing their lands; gaining also a smoother surface, where the mowing, reaping, and raking machines can work to better advantage, and against which the roots and stumps of timber land form such fatal obstacles.

Permit me to say, it is truly astonishing to witness the rapid growth of the northwestern States. With a fertile soil and congenial climate for labor, the eastern market will daily feel more and more the influence of western products upon the price of breadstuffs. There are now millions of acres of excellent prairie land fitted for the plough, and can be immediately brought under cultivation. Government land can be purchased at $1 25, and landed proprietors are offering tracts near good neighborhoods and schools for half the crops for 3 years, when a deed is executed without any cash payments. I have myself, during the year past, effected important sales on this principle, to the mutual satisfaction of both parties. Under these encouragements it is hoped that the west will continue to advance, and soon feel able to meet her engagements with better punctuality.

KILN-DRIED MEAL AND FLOUR.

This subject is of deep interest to the west, since corn meal is worth $17 the puncheon (800 pounds) in New York, and flour, from which the water is expelled, is so much more easily preserved. I visited the establishment of the Messrs. Gills, at Mount Pleasant, Ohio, and was, by their courtesy, (not granted to others,) permitted to examine minutely the whole operation of their very interesting and successful experiments.

Here I found two barrels of meal and flour, put up for me two years since; both were exposed, in an upper loft, to the heat of two summers. The casks were opened by myself, and both meal and flour were found to be perfectly sweet. I took samples of both, which I beg to leave in your office for exhibition. There are some peculiarities in the machinery and process of the Messrs. Gills, which they do not wish to disclose until their patent is secured. I will state, however, that the meal and flour are both dried, after being bolted, by means of hot air. The same thing has been attempted by other persons, but not with so much success, to my knowledge. From a barrel of flour 12 to 16 pounds of water are extracted, and a little more from a barrel of meal. Flour dried in this way has remained in New Orleans and Rio Janeiro during the hot summer months, and kept sweet, while cargoes of common flour were spoiled. There may seem to be a loss of 12 to 16 pounds of flour; but whenever the flour so treated is made into bread, it reabsorbs, as might be expected, 12 to 16 pounds more water than common flour; making in a cargo not a small saving in duties and freight, when sent to foreign markets. As staves are cheap at the west, I do not see why we cannot enter into a successful competition with the eastern manufacturers of corn meal, who have to purchase both corn and casks at comparatively high rates, somewhat greater than the difference of freight. Meal dried by hot air, has a further advantage. No change of taste in the flour is observed, nor is the hull of the corn mixed with the meal, as must be the case whenever the corn is parched, as then the hull is ground so fine as to pass the sieve. If European ports are ever opened to our breadstuffs, we can send them Indian meal—the cheapest food for their laboring classes—in a perfect state. At present the prejudices of the English people are proverbial against both Indian corn and meal. This prejudice will wear away; and as an evidence of this I would mention the cheerful relinquishment by the English, Irish, and Scotch, who migrate to this country, of their oat meal, if they can get our good sweet Indian meal. Indian meal requires particular cooking, to be good, even here. Hence we need not wonder at the unfavorable impression created by hard, clammy, dark, sour Indian meal bread from British ovens. In a late leading journal, published in England, the editor says a great deal against our maize and Indian corn meal. He "*stated from authority that it was deleterious to man and injurious to cattle;*" nor have I seen this statement contradicted there. Certainly, if corn meal offers to us, in this country, such a satisfactory repast, there can be no indignity in recommending it to those who are so necessitous, and even clamorous, for breadstuffs abroad. Since Indian corn cannot be grown in England, and hence will not come into much immediate competition with the wheat crops of landed proprietors, there is more hope of its introduction free of duty, or at least on more favorable terms. I think the time is not far distant when Indian corn will be *much* more consumed by man and beast in the British dominions. This new mode of preparing flour and meal is beneficial to government, which annually loses such sums from damaged breadstuffs. Both the army and navy, I am happy to say, will try experiments with the dried flour, and the Messrs. Gill are confident that it will keep perfectly sweet for two years, in any climate, if the article is preserved from dampness. The extraction of this dampness has given to it its great superiority, and this can only be obtained by preventing it from falling back again to its natural state.

AA.

[Referred to in the preceding remarks on hogs.]

"PETERBOROUGH, *February* 20, 1845.

"MR. ELLSWORTH—SIR: I received your letter requesting me to communicate the important facts relating to a pig raised by me the past year. I cheerfully hasten to comply with that request. The pig to which you refer was pigged February 18, 1844. I killed it January 3, 1845; of course it was 10 months and 15 days old. Its weight alive, the day it was killed, was 622 pounds—after being dressed, 547 pounds; rough lard, 18 pounds; offal, 57 pounds; total, 622 pounds. Girth around the heart, 6 feet; width across the shoulders, 21 inches; across the hips, 20 inches. From end of nose to root of tail, 5 feet 8 inches. The breed I do not know, further than that it was of a breed we have had in town for years; but should think there was no Berkshire blood in it. It was purely white, and the skin very white; hair, thin and short; short legs and short head; small, looped ears; and on the whole, a beautiful specimen of the swine.

"*Feed.*—He was taken from the sow at five weeks old, (the last week in March,) and during the month of April he was fed on skimmed milk, with a little meal. From 1st of May till the 1st of September, he was fed entirely on skimmed sour milk. September and October he was fed on boiled potatoes, apples, and pumpkins, about equal quantities, thickened with barley meal, and thinned with sour milk. November and December he was fed on corn meal scalded, once a day, and boiled corn and milk once. He was always kept under cover, and supplied with sods, weeds, brakes, &c. In addition to his carcass, he made six or eight loads of excellent manure.

"Yours respectfully,

"WILLIAM MOORE.

"This pig was fed three times a day till the last two months; and during the last two months only twice a day."

—

ON HEMP.

As regards the adaptation of Indiana and Illinois to the growth of hemp, there cannot be a doubt, and also of a large portion of the country north of the Ohio and west of the Mississippi river, as far north as the 47th degree, and eastward of the Hudson river. The price which farmers in the west would realize for a fair crop—say 700 pounds of lint per acre—would be $40 per ton in the stalk, delivered at the mill, or at $14 per acre. The cost of cultivation does not materially differ from that of corn or wheat. As regards the soil, all good prairie land will produce hemp; and bottom lands, if not too wet for corn, will afford an abundant crop. The quantity of seed is two bushels per acre, and the time of sowing from the 1st of April to the 20th of May, the ground to be twice ploughed and lightly harrowed; after the seed has been sown, harrow both ways and lightly roll. The time for cutting depends much upon the season; the usual time in your latitude for that sown in April would be from the 1st to the 10th of August; the seed should not be suffered to arrive at maturity, and the best guide for the

grower is the appearance of the blossom stalk, which will assume a bright yellow tinge near the ground, and then the knife should be applied. It should be suffered to remain on the ground, after being cut, only a few hours, merely to become slightly wilted; then bound in small bundles, and placed 12 to 15 in a shock, with the base of the bundles left open to admit a free circulation of air. Four to five days of fair weather will effect a thorough curing, and then it should be delivered to the manufacturer, or be well secured from exposure to the weather. The process adopted at one mill in Glasgow, Missouri, is to place the hemp in pools or vats, (90 feet long, $10\frac{1}{2}$ wide, and 5 deep,) crosswise; the bundles to be packed as close as possible, and well secured to prevent floating, by cross timbers at the top of the vats, before the water is admitted. At the bottom of the vats are steam pipes, passing through lengthwise, and between the pipes a water conduit, 70 feet long by 1 foot square, which is supplied by a perpendicular pipe, and perforated with holes for the introduction of water into the vats. The water, when admitted, should be at a temperature of 100° Fahrenheit, if possible; and the mean temperature during the process of rotting should be 90°. When the rotting is complete, (which is found to be the case, by this process, in three or four days at any season of the year,) the water is drawn from the vats, and the hemp removed to platforms, and placed in an upright position to drain; after which it is taken to the dry house. The time occupied in drying depends upon the quantity of aqueous matter to be evaporated; and, as a medium, 12 hours will accomplish it. The breaking and cleaning are performed by machinery. The hemp being spread upon an apron, is conducted through a series of rollers; thence on a cylinder, with crossbars, and is acted upon by beaters which intersect the spaces on the cylinder, and which serve to disengage the crushed and broken boon from the lint; it then goes to the scutcher, or hackle, and is then ready for baling. The time occupied from the period of placing the bundles in the vats, for rotting, to the delivery of it from the baling press, does not ordinarily exceed ten days. It is asked, what is the difference between American and Russian hemp? &c. I would say that so far as experiments have been made in effecting an analysis, the American has the advantage as it stands in the field; but the subsequent process to which it has hitherto been subjected destroys its richness. The fibre of the American has the preference in form, from the fact that each particle or strand is a cord of itself; while the Russian resembles a fencing sword—thick in the centre, with their edges; and this will account for the superior strength of many samples of tested American lint. The difference in climate has much to do with the matter. For instance, the temperature in Riga, during the hemp harvest, is from 40° to 60° Fahrenheit; while at a corresponding season, in this country, it ranges from 60° to 100°. Consequently, were the growth of hemp from the same soil, different qualities would be produced, even were the same operations observed in cutting and curing. The rotting process in Russia requires several months, from the fact of the water being near a freezing point for this length of time.

In the winter of 1843, I saw the same result in this country. The pools were filled in November, and remained until the middle of April; but there is no assurance of a uniform temperature at any season of the year. The preference for Russian over American hemp, at the present time, arises from the indifferent manner in which the American is cleaned and put up for market, and the absence of the vegetable oil from the lint. To obviate these difficulties, great care should be taken to avoid exposure while curing,

and also from the time the rotting of the hemp is completed until it is put up into bales. The process of drying in a close room is found to operate well, as the aqueous matter is entirely evaporated, and the vegetable oil contained in the wood or boon forced to the surface, and absorbed by the lint, and is an important life-preserver; but if the hemp is exposed to atmospheric action, the oil is entirely evaporated. The rotting process heretofore observed is quite uncertain in its operation. For instance, if the pools be filled in June, July, or August, that portion near the top will be nearly at the same temperature with the atmosphere, while that at the bottom is of the temperature of the earth, and the top courses of bundles become fermented, or macerated, while, on those near the bottom, fermentation has not commenced. At other seasons of the year, the same results are visible, though not to the same extent. The time required by this mode to effect the object, renders it a tedious and uncertain operation. As regards the difference between dew and water-rotted hemp, I am aware it is a delicate point to discuss. As my interest is involved in the water-rotting process, it may be considered a species of egotism to introduce a new system, to the injury of another. I would say, however, that such theories as I may advance are not speculative, but obtained from thorough experiments; and it is desired that every assertion made shall receive thorough investigation. The process observed by the farmers in dew-rotting, is usually to let the hemp remain in the field until the leaves fall from the stalk, and if the weather is moist, it becomes quite dark in color; but if the color is not changed at this time, it becomes so at the spreading in the fall. The lint is covered by a thick bark or husk, containing a strong acid, which, when acted upon by the oxygen of the atmosphere, forms a coloring matter which penetrates and discolors the lint, and often the wood or boon. The lint is secured to the boon by globules containing a species of gluten of a resinous character, and heat and moisture operating upon the stalk thus exposed loosen the globules from the boon, which adheres to the lint. Thus all of the gluten which grew in the plant remains in the lint in a decomposed state. This is the reason that tarred cordage has not been, and cannot be, successfully used when made of dew-rotted hemp. It has doubtless been often observed that dew-rotted hemp, after being exposed to wet, immediately decays; particularly in warm weather. This is owing to the action of the water upon the decomposed glutinous resin remaining in the lint, and fermentation at once ensues in the same form as in water-rotting. As an experiment, which you can at any time test, take an equal quantity of dew and water-rotted hemp, and leave them in an equally exposed situation, (say spread upon the grass,) and you will find that the dew-rotted will be decayed in one fifth of the time of the water-rotted. The snow-rotting, so much desired by farmers, is a process between the common dew and water-rotting. The exclusion of the air from the lint by the snow prevents the decomposition of the gluten, and the coloring matter is not formed except by a free access of the air to the stalk. The ultimate freezing and thawing of the stalk serve to disengage the lint, as in the process of dew-rotting. In the process of water-rotting at a temperature of 90°, active fermentation commences in 60 hours. The acid contained in the husk is neutralized, and a large portion of the glutinous resin is absorbed by the water. If the operation be continued, by removing the hemp from the pool, then drain and dry it in a close room and break and clean it immediately, a better article can be produced than is brought from any portion of the old world. Hemp thus prepared will

answer all nautical purposes, and also for manufacturing a large portion of coarse linen fabrics, with which we are now supplied from abroad. The quantity of hemp now imported is not much less than 3,000 tons annually; which is but a small portion of what arrives in a manufactured state.

There are no experiments to be made in constructing machinery for the manufacture of hemp and flax into fabrics of various kinds and qualities. One establishment in Leeds, England, in successful operation, occupies three acres of ground; and there are ten or twelve manufactories already established in the country. I will take the liberty to insert an extract from the report of the Commissioner of Patents for the year 1844. On the sub- of hemp he says: "The American hemp, in point of strength of fibre, durability and firmness of quality, can advantageously compare with the very best Russian hemp; but it is neither prepared, in the process of rotting, in a proper manner, nor is it even cleaned as well in the brake as it should be." These facts, together with an examination of the dark colored, badly rotted, and slovenly cleaned article, that is often sold to the manufacturer as hemp, prove most conclusively that the culture of hemp is yet in its earliest infancy. When an improvement in the culture and preparation of hemp shall be effected, there will be brought about with it a revolution in the manufacture that will tend to add even more to the general wealth and prosperity. Instead of consuming the best hemp in the manufacture of bagging and bale rope—fabrics so coarse, unsightly, and ill prepared, as scarcely to deserve the name, and in the manufacture of which we use our best material, in competition with the *tow and refuse* hemp of Europe—instead of this, our worst tow, by the adaptation of machinery to its manufacture, might be used for making a much superior article of bagging than is now made; and our good hemp would be used in making canvass or sail-duck, ship cables, cordage, and even *fine linens.* Out of hemp not a particle better or finer than ours, the finest fabrics are now manufactured in France, Germany, and Great Britain. Machinery of the most perfect kind has been in successful operation in those countries for years; and every kind of fabric, from the finest linen cambric to the coarse Dundee bagging, is there manufactured, and bought by us at high prices, when we have growing at our very doors, spontaneously as it were, the very material with which we could make the same articles, and furnish them in the whole of Europe at half the price we are now paying. As it regards the position government has assumed in the use of American hemp for the navy, the law of 1843 requires it to be tested, inspected, and purchased by agencies in the west. Thus far the requisitions of the law have not been complied with.

I would here say a few words in relation to flax, an article that has nearly ceased to have a name among the productions of our country; and if a cause can be assigned, it is that no system has been introduced to assist in its production. The process of dew-rotting has been generally observed in this country; or, if water-rotting has been attempted, it has been at a season of the year when nothing could be effected. I would say that the process as described for the culture and preparation of hemp is equally applicable to flax, and, if strictly observed, will yield a rich reward. The time of sowing is the same, and the quantity of seed should be slightly increased—say $2\frac{1}{2}$ bushels per acre. The harvesting should take place before the seed matures. It is important that great care should be observed in the curing, and also in all the manipulations to the bale press. In the present crowded state of the market with many of the products of the soil, it seems

desirable that all the branches of agriculture that will afford a good investment should be prosecuted. GEO. W. BILLINGS.

ST. LOUIS, MISSOURI.

ON BEES, &c.

BY E. G. KELLY, OF NEWBURYPORT, MASS.

No department of agriculture seems so much neglected at the present time as this; whilst the same amount of capital invested in any other branch yields less. Notwithstanding the large importations of honey and wax, at only twenty and fifteen per cent. duties respectively, the domestic supply commands a high price, ready sale, and fair profits. It appears that more than 628,000 lbs. of wax alone are annually produced in this country. Were there even no protection on the former, the foreign article would then be obtained at a rate that would enable the bee-keeper to feed it out in his apiary after the foregoing season was over, and realize a great advance for the honey in the comb. Success in the management of bees depends chiefly on a correct knowledge of their habits and instincts, thereby enabling the keeper to control them almost at will; and, also, on strict attention to their requirements, rendering them healthy, contented, and industrious. Four leading points essential to profit are yet but imperfectly practised or understood, viz: to obtain pure honey, uniformly free from brood comb; to produce artificial swarms; to prevent robbing; and, lastly, to prevent the ravages of the bee-moth. Most, if not all the pure honey, is at present obtained by placing small boxes or drawers in the upper part of the hive, in which the bees will work when no room is allowed them elsewhere; but even in these, though equally unnatural to her, the queen will sometimes lay her eggs. It is their instinct to work not only downwards, but beneath, and in continuation of old stock. They will, however, build readily in side boxes, but here the queen is almost sure to interfere. To obviate this, I have inserted small bars across the entrance to the lateral drawers, with interspaces to admit the working bees, while they arrest the queen and drones. This idea was suggested by an experiment made by Huber for a very different purpose. The least possible space through which the largest workers could pass, laden with honey and pollen, was ascertained by experiments at the entrance to the hives. The aperture allowed is a fraction less than three-sixteenths of an inch, being less than the diameter of the small cells—for which I shall claim no patent!

Artificial swarming, particularly in such seasons as the past, when bees very generally refused to swarm, has many advantages to commend it. I believe only one swarm came out in this town before the first of August, after which they are worthless. While my neighbors were in daily expectation of swarms in the usual way, with their drawers closed till too late to obtain much honey, I had three stock-hives arranged over empty hives, and the bees busily at work. On the 12th of June, a young brood was discovered in one of the bee hives, then two-thirds filled with bees and comb; the old hive was at once removed to another stand, still placed over a second hive or box, and then shut up for twenty-four hours. A cover was secured upon the other, and the bees confined thirty-six hours. New comb

was rapidly formed in the second under box, and the old one was again removed in like manner. On the 4th of July the old swarm was driven into a third box, leaving 50 lbs. of honey. A drought soon checked the usual supply of moisture, so that the second and the transferred swarms required feeding for their winter store. I divided a second stock the 25th of July; but being in doubt if the lower hive contained any brood comb, I immediately expelled the bees from the stock hive into an empty one, using tepid water in order not to injure the young bees, which it contained in abundance. This brood-comb being in a large old-fashioned hive, was cut down to 12 inches square (the size of the new ones,) and arranged in two of these. One was set over the transferred swarm, which immediately ascended, and, having a queen, took quiet possession. After twenty-four hours they were allowed to roam abroad, returning to their new home, ten feet from their former stand. The other box, containing the old comb, was placed over the bees at the old stand, and a communication opened. They reared a queen in due time, as did also the two that had been separated from the first stock hive, the cells of which were distinctly seen in each.

It is not uncommon for one swarm to rob another, especially in an unproductive season. In this respect I was vexed for weeks, through carelessness in exposing honey in the comb to common access. Myriads of my own and neighboring bees destroyed each other in the contest, till the honey was removed, when the latter made a vigorous attack upon my hives. Narrowing the entrance is the principal remedy given by writers; but in one instance this did not succeed. During the second, the queen in the infested hive was constantly croaking as if held prisoner, and at night but little honey could be seen. The bees also were greatly diminished by the combat, and perhaps by being enticed away. Early the next morning the robbers returned in great numbers, meeting with but little opposition. Finding the queen yet alive, and anxious, if possible, to save a favorite swarm, I closed the mouth of the hive and drove with it a distance of three miles. This was of course effected. At night I determined to try another experiment. I swept $3\frac{1}{4}$ pounds of bees hanging out of another hive into an empty box, and took them to the rescued swarm. These were united by placing one above the other, and fumigating both effectually with cigar smoke. No disagreement was observed, nor was it possible that but few, if any, found their way back, even of the robbers. In six weeks they were returned to their former stand, having apparently collected more honey than any one at home. Thus it will be seen that transferring and equalizing swarms may be as readily effected as dividing. In each operation the precaution should be taken to have a free circulation of air.

The great pest to the apiarian is the bee moth. No device will entirely prevent its incursions, without great care. Loosely twisted yarn, thickly studded with its woolly fibres, has completely protected the crevice between the hive and its bottom. Hives are not safe either on the ground or in the tops of buildings. I have tried them in the second story of a barn, the bottom boards projecting through, but around these the larvæ of the moth were frequently discovered. Another decided objection to such an elevation is the great difficulty the bees meet with in lighting upon the pedestals when returning heavily laden and fatigued, particularly in a high wind. When a swarm is unable to dislodge the moths, both bees and honey have hitherto been a total loss. By the use of the tunneled bottom, the existence and progress of the larvæ of the moths may be known and watched

by observing the size and quantity of their black oblong fæces, which falls down with bits of comb, &c. By this means I first discovered that the hive containing the old brood already described was thus doomed. The bees were at length transferred to an empty box and placed over a small swarm, with a sheet-iron plate drilled full of holes between them. At night, after the atmosphere of the two was sufficiently commingled, the divider of the two was removed, and the swarms united. No quantity of fæces was observed among the workers, and a few only hovered about the place of their former stand the following day. The moths had burrowed chiefly in the old comb. They evidently commenced their depredations where a bar entered the hive to confine the comb, which in the hurry of the operation was imperfectly adjusted, and the strong odor of the old wax attracted the parent miller. Most of the worms were drowned in the tub, and the honey was saved for feeding other swarms. The simplest out-door arrangement for hives is undoubtedly the best for bees, while it affords the least harbor for moths. My stand is constructed of joists, seasoned, planed, and painted, 20 feet long, fastened a foot apart upon three posts two feet high. Three such pieces of iron rods are so set upright in this frame that four will support a hive. The tops are filed to points to receive the bottom firmly. The hives are protected from the heat of the sun by trees, and in winter may be removed to an outhouse. I am convinced, from a very limited experience in the management of bees, that this plan is better than housing, unless the moth can be entirely excluded.

The tunneled and canaled bottom, recommended by Thomas Affleck in his work entitled "*Bee-breeding in the West*," is one of the greatest improvements in the apiary. His "subtended" or section hive, consisting of boxes a foot square, inside measure, placed one above another, I have also adopted, with the addition of glass, and the frames made use of in the "Russian hive," and his bottom, with the entrance enlarged three or four inches. I also use under-hives, with drawers. These are made $2\frac{1}{2}$ feet long, $1\frac{1}{2}$ wide and deep, including seven drawers, two on each side and three at top, with glass backs and hinge-doors.

Yours, &c.,

E. G. KELLY.

ON HOT-BEDS.

BY DR. MUNDER, OF NICOLET.

Take white cotton or calico of a close texture, stretch it, and nail it on frames of any size. Take two ounces of lime, four ounces of linseed oil, two ounces of white of eggs, two ounces of yolk of eggs, four ounces of finely powdered dry cheese. Mix the lime and oil; break the eggs well, separately, then mix them with the oil and lime, with a gentle heat; and, lastly, add the cheese, and stir it well. Spread this mixture over the cotton shades with a brush, allowing each coat to dry before applying another, until they become water-proof. I made several attempts according to the foregoing form, slightly varying it each time, but with the same unsatisfactory result—a thick mass, about the consistence of stiff mortar, which it was impossible to lay on with a brush. I lastly substituted two ounces of

strong lime-water for two ounces of lime, and mixed the other ingredients, excepting the cheese, in the heat of the sun. If greater heat be applied, this compound also will become a thick mass. The cheese only serves the purpose of filling up the interstices in the cotton or calico, if it be of open texture. The stuff I made use of was of very close texture, and did not require the cheese. The application of this composition renders the cotton semi-opaque, or like the ground glass shades. Among the advantages these shades possess over glass ones, the following may be mentioned: First, the *cost* being hardly one fourth of glass; next, breakage—if any accident happens to the calico, a needle and thread, and the composition, repair the damage. Next, the *light*—the shades require no watching; no matter how intense the heat of the sun, the plants are never stricken down, burnt, or faded, and therefore never checked in their growth; nor do they grow up long, sick, and weakly, as they would under glass, and still there is an abundance of light. Next, the *heat*—the heat, arising entirely from below, and being less influenced by the sun than when glass is made use of, is equable and temperate; which, in our variable climate, is a great object. The vapor arising from the manure and earth is condensed by the cool air passing over the surface of the shade, and hangs in dew-drops on the inside of the calico. I gave the experiment "a fair trial," in the fullest sense of the term, having laid down both calico and glass, with the same manure and heating, the same seed, and under the same aspect—southwest; and the result was, that the plants raised under the calico were stronger and healthier than those under the glass. The calico shades were always in advance of the college hot-beds, which are under the care of a professed gardener; as, also, of all the other gardens in this neighborhood. If the frames or stretches are made large, they ought to be intersected with cross-bars about a foot square, to support the calico, and thus render it less liable to injury.

Throughout the frosts of the last three weeks, the heat of the beds under the shades has not been checked for an instant.

MODE OF RAISING MUSTARD.

BY J. H. PARMELEE, OF DUNCAN'S FALLS, OHIO.

The *ground* should be light, lively, sandy loam, rich enough to produce fifty bushels of corn to the acre; ploughed as early as it will do to work; the tops of the furrows levelled with a light bush. This makes it easy and even for working the drill-barrow.

Sowing.—I use a drill-barrow—one with two large light wheels, easily worked by hand, made by Ruggles, Nourse, and Mason—cost fifteen dollars in Boston—ingenious, simple, and durable inplement. With this (supposing the lines from top to bottom to be the direction of the rows) lay them first one foot apart, then two feet, so alternating them thus, , and have the hole in the tin plate, through which the seed falls, of a size sufficient to drop three pints of seed to the acre. Begin with the plate which has the smallest hole, and ascertain the requisite quantity of seed by observation of the first, second, or third half-acre, decreasing the hole if necessary, to adjust its size to the quantity.

You will see the advantage of the rows laid off as above by inspection of any given number of feet—say sixty-six feet.

The difference in the number between the manner above and single rows at two feet distance is the *profit*, and the growth of the plant in the former way no more than fills the atmospheric space; whereas, in the latter it looks too thin and poor. These double rows have another important use, as will be seen presently.

The largest yield per acre of corn ever raised in Ohio was on the above plan, one foot and four feet, drilled—stalks, nine inches in the row.

Three pints of seed per acre makes the plants stand very thick; but, no matter—nature adjusts the distance and size of the stalks to the strength of the land. The undergrowth that is smothered helps to smother the weeds also. Therefore, let no thinning out be done.

Culture—As soon as the weeds peep above the ground, which is as early as the plant, and before it is large enough for a cultivator to pass between the rows, the fields must be plentifully stocked with hands, having light hoes and nimble fingers, to attend to the rows only, otherwise the weeds will be apt to smother the crop, which is very slow in its early growth. And these hands and cultivators must continue going over and over the field, (if it be large and the weed bad,) say four or five weeks, until the plant springs up and blossoms and branches, so that further working would be injurious to it.

Cutting.—When the leaves have all fallen off from the stalk, and it turns yellow, and the seeds in the pods, which are near the ends of the branches, are changed from a deep green to a brownish color, for the most part, through the plant and through the field, or such parts of it in which it will do to begin, then cut it immediately with the sickle, (cradling, which I have tried, would knock out the grain,) tenderly handling it, and laying that cut from two double rows upon the stumps of one, in heaps. These stumps form a fine support for the grain clear from the ground, and admit a free circulation of air under it. Let it lay three or four days until it is bone dry—or for a week, if you please—until you are ready to take it up for threshing. If rain come upon it, no matter—it will not hurt it.

Housing.—According to the extent of the field or force, have one or more canvas sheets of light hempen duck, 24 feet square. Clear a space and spread it upon the ground in the field, supporting the corners and sides by small stakes about the height of two feet. On this place top to top the heaps that lay around, or that may be drawn a short distance on a sled, furnished with a sort of hurdle of poles, to support a canvas sheet on that also. Thresh with flails. Four men can work to advantage on one sheet—three to thresh and one to turn and shake up. The heaps of grain should be taken close to the butt-ends of the stalks and lifted perpendicularly up, not dragged or gripped hard by the hand—otherwise much loss will ensue. When the sheet is charged with as much grain and chaff as can be conveniently handled, tie up and haul it to the barn floor, and then the canvas may be spread on another part of the field, if desirable, and so through.

Curing.—At the barn should be a hand to rake the bulk of the chaff from the seed as it is delivered, otherwise space will be wanted; and the seed, being at the bottom, will be prevented from drying. The hand must work *without shoes*, and rake the chaff from side to side repeatedly off the floor—every time sweeping the space clean before removing the chaff back to the opposite side, to be sure that no seed is thrown out with the chaff.

After such raking, the seed should lie in bulk in the remainder of the chaff and dirt (which keeps it from packing, and sweating and heating) for three weeks, and be thoroughly shovelled up and removed from side to side every day. By this means the seed cures bright and dry. Then pass it twice through a farming mill, furnished with a riddle No. 12, and the article is ready for market.

The foregoing is the result of fourteen years' trial in every form—in rows at different distances, broadcast, mixed with clover seed, with the view of smothering weeds, on different soils, at different times of year, &c.—and is the only method that was ever successful with me.

It seems to me that the agricultural community, both of the north and south, will be apt to complain of over-production, so long as its attention is wholly absorbed by a few leading and important objects, to the entire exclusion of various minor and profitable interests. In our goodly land, stretching through so many climates, we have a spot, and a good spot, for every production of the temperate zones of both hemispheres. An examination of that great work of the Secretary of State (his report of 1842, "on the commercial relations of the United States with foreign nations") shows us that we might very profitably transplant into our own genial climate various fruits, costly drugs, and valuable materials for manufactures, with a special view of exportation to other countries, without reference to the supply of our own country, where the demand, however, would be large and permanent.

And your own report shows (and in behalf of the industrial interests of our country, I am thankful for your valuable labors) that mechanical inventions, in their bearing upon agriculture, will soon place us on a level, as to cheapness of production, with those countries that are filled with coolies, serfs, and slaves.

Yours, &c.,

J. H. PARMELEE.

March 22, 1845.

Sir: You have in detail the process pursued by me in the cultivation of mustard in 1844.

As you want facts, I think it not amiss to state to you that I have followed the same process, in a like enterprise, the past season.

I planted 28 acres with brown, and two acres with white mustard seed. Of the former the yield was 305 bushels, and of the latter 15 bushels—320 bushels in all; which was 61 bushels less than from 27 acres of the same ground the year before.

The whole expense of the crop this season, delivered in New York, was $1,089; for 298 bushels I received $1,117. The article being plenty in the market, I was obliged to submit to a reduction of one cent per lb. from the price of last year.

This diminished quantity is to be ascribed to the capriciousness of the season, the weather having been either too dry or too wet, alternately—the reverse of that which the different stages of the plant required.

Comparatively, the result was fortunate, as several undertakings of the same kind around me proved entire failures; owing, I judge, to the neglect of seasonable and thorough tillage.

I am, very respectfully, your obedient servant,

J. H. PARMELEE.

Hon. H. L. Ellsworth.

LETTER OF MR. LEWIS, ON COLZA.

Dear Sir: The acquisition of any new branch of industry to a nation whose population and territory are so extensive as ours, will be hailed with pleasure by every true friend to his country; and it is a marked feature in the character of Americans generally, that they are always prompt to avail themselves of every useful improvement in the arts or sciences, no matter from whence it emanates. We perceive almost every year the development of some new product of agriculture or the mechanic arts. Under circumstances of great difficulty and discouragement, we have thus seen the gradual increase of our iron mines; our silk and wool growers; the opening of our vast coal regions; the extension of our foundries and machine shops, and remarkable and striking improvements upon the ingenuity of the old world, produced by the very obstacles and difficulties that embarrassed our earlier steps in each and all of these industrial pursuits. The dense population of western Europe, whose vast mass are so dependant upon the various products of agriculture for the staple commodities of subsistence, require at the hands of the cultivator a higher degree of knowledge in the practice of his art than is expected, or we may even say needed, from the American farmer of the present day. The irrigation and drainage of land, the chemical composition of manures, the alteration and fertilizing of soils, are now reduced to a system in many parts of Germany and France—a system that we shall attain whenever our necessities develope its value. The cultivation of the beet root in France is an evidence of what improvements the wants of a people will produce; and the same remark applies to the cultivation of the family of seeds, that are so productive of oil; an article that modern refinement applies in a thousand ways, and which ministers so directly to our comfort, when used in the production of artificial light. The present magnitude and importance of this branch of European agriculture may be traced to the destruction of the fisheries of the Atlantic seaports during the long continued wars of Napoleon. The necessity of a supply of oil for domestic as well as public uses encouraged the farmer to the cultivation of the rape, colza, and other seeds known to be capable of yielding a sufficient quantity of oil to pay the costs of production. And the continued absence of all kinds of fish oils from the market enabled those who attempted to make good this deficiency from the seeds of the earth, to mature their experiments, and, after much difficulty, find a method of culture that would repay them for their labors.

In a tour through various parts of Belgium and France, in the year 1844, I saw extensive plantations of the colza, which is a species of cabbage, defined by botanists as the *brassica campestris oleifera*, that produces a very excellent oil for combustion and other purposes. Upon inquiry, I was surprised to learn that this seed, and the oil expressed from it, is now considered one of the great branches of national industry, both in Belgium and France. So extended has its culture become, and the crop of oil is so abundant, that it is afforded at prices which I should suppose would effectually prevent the entrance of sperm oil as a competitor in the market. Observing that the soil upon which this seed appeared growing was by no means of the best description, I afterwards learned that the plant is so hardy that it will flourish even in a poor soil, though the crop in such cases yields but

lightly. In the belief that this seed might be successfully introduced into the United States, and that, if not now, we may hereafter derive some advantage from its culture, I procured a quantity, together with a treatise upon the method of cultivation, written by an eminent agriculturist, who has for many years given close attention to this subject, and is considered the highest authority as to the peculiar management of the plant.

It gives me great pleasure to have the opportunity of placing a translation of this treatise in your hands, together with a sufficient quantity of the spring and fall seed to enable you to supply many of your correspondents, who, I doubt not, will be willing to make trial of the plant, and ascertain how far it may succeed in our climate.

The oil of colza is, in its saleable condition, a clear, limpid fluid, of a specific gravity nearly equal to sperm oil, and one of the richest hydrocarbons from any of the family of oleaginous seeds. It was owing to these qualities that the French government long since adopted, and still continue its use in all their light-houses, which are estimated to consume, in the aggregate, 32,600 gallons per annum. The Belgian and Dutch governments also use it for a similar purpose; while the salons of Paris and Brussels are illuminated by its means. A perusal of the annexed translation will show that the culture of the colza plant is a very simple process, though requiring considerable care in the outset, until the nature of the plant is fully understood. There are, it appears, two plantings during the year, viz: in the spring and fall; with a transplantation of each, when the plant has attained a proper size. I have omitted no portion of the *instructions* that relate to the work in the field, but have left out a long and unprofitable portion relating to the threshing and storage of the grain, as well as a description of the windmills used for grinding; knowing that our farmers are well qualified in the art of securing their crops, and that wind is not used as a motive power in this country, where water power is so common. There are two kinds of mills used for expressing the oil from the seed after it is ground. The first is the hydraulic press, the same as used for sperm oil. The second is called the Dutch wedge press, or crushing machine, a very clear description of which may be found in the supplement to Ure's Dictionary of Arts, &c. The seeds of the French colza yield about 40 per ct., or two-fifths of their weight in pure oil, whose specific gravity is 0.9136, (sperm oil having a specific gravity of 0.9231.) It burns with a clear bright flame, with much less incrustation upon the wick than occurs during the combustion of sperm oil or lard, all animal oils being somewhat troublesome in this respect. The article is sent to market in small barrels, containing, by French measurement, one hectolitre, which is one hundred litres; and, converted into English wine measure, is 26.4 gallons. The market value of this oil averaged, during a period of 10 years, 92 francs per hectolitre; which, reduced to our currency and measurement, is about 69.6 cts. per gallon.

M. Fresnel, the chief engineer of the French light-house service, made a careful series of experiments, some years since, to determine the economical value of the oils of colza and sperm—that is to say, which of the two consumed the slowest in lamps producing flames of equal size and intensity; and he found the difference so trifling as to be unimportant. Similar experiments were tried at Edinburg by the engineer of the Scottish light houses, who states, in his report on the subject, that the difference is neary one fourth in favor of sperm; which result appears the most correct of the too, and I

have no doubt it is so. If the soil of our western prairie should prove congenial to the colza seed, it would seem as if that were the most appropriate region for its culture, where the farms are usually extensive and crops abundant. The principal difficulty seems to be in the transplantation necessary to the production of the crop, and the amount of labor which such a process necessarily involves. If, however, our farmers were merely to raise a small quantity, and a market were once established for the seed, the oil crusher would soon appear among the list of our manufactures.

I remain, dear sir, yours with great respect,

J. W. P. LEWIS.

Hon. H. L. Ellsworth.

Treatise on the cultivation of the Colza, or Brassica Campestris Oleifera, as practised in Belgium and France; abridged from the original of M. Hotton, Agronome Cultivateur Belge, Ancien rédacteur du Journal des Forêts, Auteur du Manuel de l'Elagueur, &c., &c., &c. By J. W. P. Lewis, C. E., 1845.

Culture.—Colza is a variety of the cabbage. It produces an oil generally used for illumination, but is also employed for many other purposes.

The yellow flowered colza, designated as the cold colza, is the only kind raised in Belgium or Flanders. Almost every variety of soil is adapted to the growth and profitable cultivation of this plant. Good soil will of course produce more abundantly than poor; but, in some years, as large crops are produced from soil of medium quality as from the best, hence the importance of improving soil of the former description. The above remarks are applicable only to the cultivation of the colza that is to be transplanted; the sowed colza, on the contrary, requires a good soil, and one that is in a fair state of cultivation; consequently not exhausted by previous crops. Thus the cold colza can be transplanted to all soils after the harvest of wheat, rye, and oats, while the grain that is sowed in general yields but poorly, except in the best soil. This difference in production arises from the fact that the sowed colza derives all its nourishment from the ground in which it is sowed, while the transplanted colza has the benefit of two soils. Further explanation on this point will be found in the following remarks on the period for sowing and planting colza.

Planting.—Colza designed for transplantation is commonly sowed in July—a little earlier or a little later, according to the state of the weather. The success of the crop depending upon the vigor of the plant, care must be taken to get those plants that are in a good and healthy condition. This may be effected by sowing early and rather thinly, though then there is some danger of the colza blossoming before transplantation; while, on the other hand, by sowing late there is equal danger of the plant being feeble at the proper time for transplantation. It is a difficult thing to obviate these matters in a general way; the only probable remedy is to choose a favorable spot of ground, and bestow particular attention upon the irrigation of the seed. Colza is generally transplanted during the months of September and October; more often in the latter. The sowed colza is generally sowed towards the end of August, or during the month of September, according to the weather. The seed should be cast at distances of about one foot.

March colza (colza d'Eté) is sowed from the 15th of March to the 15th of April. At this period the seed must be cast deep, to prevent it from being destroyed by insects. Colza sowed in July is always designed to be transplanted in September. The ground must be well ploughed and abundantly manured; then harrowed, and the seed thrown in small quantities. When too thickly sown, a thin and long stalk is the consequence. A good plant should be firmly rooted, with a thick and rather short stalk—say about one inch and a half in thickness, and a foot in height. The harrowing is indispensable, as without it the seed would sink too deep, and would thus be prevented from coming up uniformly. Colza is planted either with the spade or with the plough. Many give the preference to the former method, but we think without reason, for it is only with considerable difficulty that the stalk can be well planted in holes made by the spade, while in ploughed ground it can be planted with ease at a sufficient depth to be protected from the frost—a consideration of the utmost importance.

The ground intended to receive the transplanted colza should be twice ploughed; the first time as soon as the crop of wheat or oats is taken off, the second at the time of transplanting. The latter ploughing must be so managed as to leave beds of eight to ten feet in width, over which the harrow is drawn with the teeth upwards, in order to smooth the surface. In these beds holes must be made with the spade in as straight a line as possible, and the plants inserted in them. There is no objection to transplanting in the driest weather; on the contrary, though the plant may, in consequence of the dryness, droop for a while, it springs up with more vigor after the first rain.

Four or five weeks after transplanting, the process of hilling must be gone through with. This is done by digging a ditch about a foot square in depth between each row, and by throwing the earth taken therefrom about the roots of each plant. The foregoing remarks are equally applicable to spade planting. To plant with the plough, it is only necessary to insert the plant in the furrow, and cover the roots with earth.

Sowing.—It has already been remarked that the sowed colza requires a better soil than the transplanted. The preparation of the ground, however, differs but slightly.

As soon as the crop that precedes the colza is taken off, the ground must be ploughed, and shortly after harrowed. The same process must then be gone through a second time, the seed put in, and a light harrow passed twice over the ground; after which it must be rolled. This being done, furrows must be ploughed at intervals of about eight feet, and, as far as possible, they should be drawn on a slope, in order to drain the ground. About two months after sowing, the hilling (the process of which has already been described) must be commenced. It is desirable to preserve the clod cut from the ditch entire, it being very efficacious in protecting the plant from frost; and this being done, no further care is required.

Colza should be sowed as soon as possible after the crop that precedes it (most generally oats) is cut; and, in order to avoid loss of time, the oats should be gathered into sheafs [ricks?] placed upright, with sufficient space between to admit the plough and harrow. By this means the ground can be prepared for the seed without waiting for the previous crop to be taken away. March colza is, however, though of an inferior quality to the winter colza, held in estimation, from the fact that the crop, not being exposed to frost, is more certain in its results. It requires a good and moist soil, and is generally sowed from the 15th of March to the 15th of April.

Harvesting.—The period at which the grain becomes ripe varies according to the weather. Most generally, however, the time for gathering it is about the middle of July. The period of maturity may be known by the leaves, branches, and seed vessels assuming a *whitish* appearance. Great care must be taken not to cut the plant prematurely, as on this point depends, in a great degree, the success of the operation. When too ripe, a large quantity of the best grain is liable to be lost; and when too green the *quantity* of oil is much diminished, and the *quality* becomes poor. The plant is cut, with a sickle, about five inches from the ground. The reaper generally stands in the furrow and cuts on either side; this method being found to hasten the work very considerably. When the weather is dry, the cutting should take place only very early in the morning, because the seed vessels being then closed, prevent the grain from falling out, which is not the case later in the day. The plant being cut, it is left to dry, and this is accomplished in from two to four days, according to the weather.

Threshing.—The grain is threshed in the same manner as wheat, and winnowed after this operation. The bulk of the stalks is generally preserved for fuel, and the residue burnt on the ground—the ashes being valuable for bleaching purposes.

The preservation of the grain requires care, it being subject to fermentation if heaped up too thickly when newly threshed. The fermentation may be readily detected by the grain assuming a whitish appearance. To avoid this, it must be spread out so as not to be more than one inch thick, and must be turned every day for a week; after which, it may be formed into heaps of six or eight inches high. It must, however, be turned pretty frequently during the whole time that it remains in the granary.

The spade being of great importance in the cultivation of colza, it may not be amiss to state that the most approved instrument of this description is that called the Belgian spade, the blade of which is an oblong square, concave in its entire length; the socket solid, but not very thick; and, when the handle is in, the whole instrument forms a slight curve.

Manufacture of colza oil.—The extensive use of windmills in France and Belgium for grinding the various sorts of grain, has grown out of the absence of suitable water-powers in many of the richest agricultural districts. The steadiness of the latter as a motive force, renders it at all times preferable for such purposes. The machinery commonly applied in the reduction of the colza seed to a meal, suitable for the oil press, is composed of a pair of vertical millstones, running on a horizontal bed stone, enclosed in a circular wooden hopper or tub. The two vertical millstones, which are of granite, revolve on stout axes, passing horizontally through a vertical central shaft, upon the head of which is a large spur-wheel geared into a smaller one, the lower end of whose shaft connects with the water-mill by a pair of bevel gears. The two vertical millstones are thus made to travel round the circular bed stone, and by their weight crush the seed into a coarse meal. The operation is continued until the meal is of a suitable fineness to go through the next process. Before putting the seed under the operation of the edge stones, as above stated, it is found advantageous to pass it through a bruising mill, which consists simply of a pair of iron cylinders, turned smooth, and made to revolve so as to bruise the seed as it drops between them from a hopper placed over the opening above them. Scrapers are fitted to the under surface of each cylinder to remove any oil cake that may form upon them. This operation of bruising the seed is very necessary, because the

unbruised seed will slip away from under the pressure of the edge stones in grinding, and thus retard the operation very considerably.

The next step, after the seed has been ground to a mealy paste, is, to remove this immediately into the press when cold drawn oil, of fine quality, is wanted; but, for general purposes, the paste must be heated before pressure, as the yield is greater, and more easily obtained. The oil cake, from the first pressure, is passed through the edge-mill a second time, then heated up to 212° of Fahrenheit, before receiving a final pressure. The apparatus for heating the seed paste, which best fulfils the purpose, is that of Hallette, and consists of a pair of iron kettles, concentric, one within another, the space between being formed into a steam-tight flue, with an induction and eduction pipe to admit or blow off the steam with. A gate-valve opens on one side of the kettle to draw off the seed, while hot, into bags of hair cloth, which are then immediately subjected to pressure. *Stirrers* are made to revolve in the kettles by machinery. The hydraulic press and the Dutch wedge press are the two machines that are used in the extraction of oil from seeds; some prefer the former, while many assert the latter to be most applicable to this purpose. The best fuel for heating the seed, where steam is not used, is found to be coal dust made into cakes, as the heat must be raised slowly and kept low.

The manufacturer of oil who would economize in the article of barrels, and, at the same time, prevent losses by leakage, generally constructs a deep cistern of brick, laid in hydraulic cement, and plastered inside with the same. This cistern should be of a sufficient capacity to contain all the oil that is not intended for immediate transportation. Such cisterns are used in Tournay, and are found to answer in every respect.

The colza oil undergoes a final process of purification in the hands of the oil merchant, but this is beyond the province of our treatise.

The experience of many years has proved to us that the cultivation of this seed in Belgium, Flanders, and France, may be safely entered upon as a branch of industry that, under judicious management, is sure to repay those who make the enterprise, and the annual extension of its culture is the best proof of the truth of this opinion.

APPENDIX No. 2.

For the Prairie Farmer.

SMUT IN WHEAT.

BY A. L. CASTLEMAN.

Messrs. Editors : I am very glad to see the subject of the causes of smut in wheat discussed in the two last numbers of your paper, and propose to have the discussion continued by adding my mite of experience and observation. First, then, to Mr. Hardup I say the plan recommended in the March number of the Farmer is excellent—probably the best one now in use. But as scientific farming is in its infancy, it is right that we should be correct in theory as well as in practice, else the utility of our discovery stops with its first application ; whereas, on the other hand, if our theory be correct, or, in other words, if we attribute an effect to its *proper cause*, we are enabled to apply the same fact to other subjects, and with our eyes opened as to what we are about. Now, how do brine and lime prevent smut in wheat? By destroying the *vitality* of the sporules, says Mr. Hardup. Let us see. On the farm on which I now live, the gentleman of whom I purchased it sowed about five acres of wheat, (on the sod,) and so careful was he that he went some distance to procure seed free from smut. This he did, and sowed it. I saw it at harvest—it was very smutty, although the season was not one in which smutty wheat prevailed to any great extent. The grain was sown late in the season, and was immmediately followed by a light rain and cool weather, which much retarded its "coming up." The spring following, this same five acres of ground appeared so handsomely set with wheat, from the self-sowing of last year's smutty crop, that the owner concluded to let it grow and see what it would do. At the harvesting of this crop I owned the farm. Although it was a summer in which smut prevailed to a greater extent than I have ever known it (1843) in this country, yet this self-sown smutty wheat, on five acres, produced scarcely a smut head. In this case, what became of the sporules which are said to be "taken up by the sap vessels?"

Again : In the fall of 1842 I sowed wheat on the same farm, and find the following amongst my "notes on farming" for that year :

"On the first and second days of October I ploughed and dragged three acres of oat stubble—land in fine order. On the third I sowed two bushels of Egyptian wheat on an acre of it, and dragged it in. From this acre, notwithstanding the lateness of the season, I got a good crop of wheat, (20 bushels,) but rather smutty. On the twelfth, the other two acres were sown in the following manner : On one acre $1\frac{1}{2}$ bushel red chaff bald wheat, ploughed in. From this acre I got a yield of $18\frac{1}{2}$ bushels, and nearly as much smut as wheat. The remaining acre was on the the same day (12th) ploughed a second time—a bushel and a half of the same kind of wheat sown after ploughing, and dragged in. From this acre I got $22\frac{1}{2}$ ushels of clean plump wheat, almost entirely free from smut. What could have made the difference ? All my seed was prepared alike, brined and died, by rolling in ashes; the different pieces of land were equally good, and sown in equally good order. Can it be that the deep covering with the

plough at this late season weakened a part of this seed, and that this weakened portion produced the smut?"

The above is a quotation from my note book. I think we can spend a few moments profitably in recapitulating the above facts.

The first sowing to which I have alluded was done in October, followed by a rain and cool weather—the seed lay chilled a long time before it came up—the produce was smut from clean seed. The second sowing (self-sown) must have taken place in August, when the ground and weather were warm—the seed must have started immediately—the product was a clean plump berry, from smutty seed, without either liming or brining. Next, we say nothing of Egyptian wheat spoken of in the quoted notes, as that might have been more or less liable to smut than other kinds of wheat. But of the second kinds sown on the same day, from the same seed, prepared alike, and on like soil, we see that covered to the depth of three or four inches producing largely of smut, whilst that sown on top of the ground produces scarcely any. Another fact worth noticing—these two acres were sown the same season of the self-sown smutty wheat, and within twelve rods of it. Now, I ask any man to look over these facts, and say what he thinks is the cause of smut in wheat. I am a new farmer, Mr. Hardup, but have given much attention to this branch of the subject, and shall give more; and should I be so fortunate as to bring to light any facts worthy your notice, you shall have them, provided the Prairie Farmer will consent to become the medium of communication.

One request of you. Will you inquire of all your neighbors whether any have a distinct recollection of having raised smutty wheat from a self-sown crop, and communicate?

From the Cultivator.

RUST ON WHEAT.

Ed. Cultivator: Investigation would seem to have established that *rust on wheat* is a small plant of as regular and uniform a growth as wheat; and if such is the fact, any speculation on the subject would be useless. But if so, the rapidity of its growth, visible to the naked eye, is truly astonishing, and any information concerning that growth must prove interesting to the community.

Four years ago, the writer had on his farm in Tompkins county fifteen acres of beautiful wheat. The field was the admiration of all who saw it. It stood thick on the ground—was as tall as was desirable; the heads were large and long, and it presented a rich and beautiful appearance. It then promised from thirty to thirty-five bushels to the acre of superior wheat. This was the first week in July. The weather then became very warm, and for three days there were frequent light showers, with bright sunshine between them. In the language of the farmer, it was close, oppressive weather. Before the commencement of the rain, there was not the least appearance of the rust upon any of the wheat. On the contrary, it then promised one of the finest and heaviest crops ever raised in this State; but in less than four days the whole field was stricken with rust, and the result was twelve bushels to the acre of shrunken, instead of from thirty to forty bushels of superior wheat to the acre. The land on which it was grown

was a rich clay-loam, with a small portion of gravel, rather moist than otherwise.

The lot is situate near a creek of pure spring water, and during and immediately after the rain a fog was discovered above the stream, and also above other streams in the vicinity. All the wheat growing near those streams was much injured by the rust; whereas that which grew half a mile distant from them remained uninjured. Seven acres of mine growing on new ground, one hundred and fifty rods from the stream, escaped entirely; but it was sheltered by woodlands on two sides, and the ground for the most part was dry.

The first crop on this fifteen acres gave twenty eight bushels (wheat) to the acre; the second, (oats) forty; the third, (corn) one hundred bushels of ears; the fourth, (oats) forty; the fifth, (wheat) after oats the same season, twenty—all the finest of grain and no rust to cause injury. It was then stocked down with clover, and summer fallowed the second season for the wheat which was so seriously injured by the rust. If, as is maintained, rust is a plant, whence came it in three days? It was not wafted by the wind, for there was none; it being remarkably calm, damp, warm and sultry, and the sun between the showers shining intensely bright. But if it be a plant, for its growth, so as to injure wheat, it requires calm, damp, warm weather, and such weather must occur when the wheat is in the milk, or the grain soft. Some of our observing farmers say that if the rain is accompanied by wind, the rust does not injure the wheat.

My belief is that the rust plant or fungus, whatever it may be, always exists on the stalk of the wheat, but that its growth is not such as to injure the plant unless warm weather and moisture unite at a particular period during the growth of the plant, and that prior to that period it is not visible to the naked eye; also, that during seasons unfavorable for its production it does not attain maturity. If, for example, the grain has passed the milky state, and has become in a degree hard, then the rust will not injure it in the least, however favorable the weather for its production may be.

In confirmation of this, he would remark, that during the most part of July last, in this section, the weather was very dry and warm. Yet about the 15th of the month, we had some wet, warm weather, and the consequence was that most of our fields of wheat were stricken with rust; but the berry was formed when the wet weather commenced, and the wheat was too far advanced to be injured—the rust proved too trifling to cause injury—the wet and warm weather was not perhaps of sufficient duration. The showers were short, and the rust did not so far progress as to stop the circulation of the sap, and the berry obtained the necessary supply.

Our crops of wheat have not been so fine for many years—the berry is large and the wheat of a superior quality. Even the late sown wheat, although affected by the rust, has escaped injury. The berry is not inferior to that sown earlier, but the yield to the acre is not so great by one-fourth. Superior cultivation and early sowing are the best preventives of the injurious effects of rust yet discovered. But the writer believes he has discovered a remedy for the rust, plant or no plant. He is preparing to make the experiment the next season; and if successful, the result will be communicated.

He also believes that great crops of wheat may yet be grown as well in the counties on the Hudson as in western New York. We shall see.

A Farmer of Tompkins County.

From the Dublin Evening Post.

"Smut in wheat is of two affinities to the growing crop in which it is found: the large full-eared smut, equal in growth, in luxuriance, and, at first sight, equal in all respects to the healthy ear beside it; and the small, stunted, and comparatively innocuous smut. How are these two species of smut produced? The argument in one case will hold good in both; we shall, therefore, confine ourselves to the full-eared fungus. The grain of seed, in this case, is equal in size to the sound grain, but diseased from some accident, either while on foot in the field, by an untoward season, such as the present has been, or by damp in the sheaf while in or after having been removed from the field, or by any one of the thousand accidents to which it is liable before it is committed to the earth to germinate, in the hope of producing its quota of a new harvest. Now, we will suppose it to have been injured by moisture, no matter from what cause—the effect is sure to be the arousing of the incipient powers of germination; the acrospire [plumule] will swell and make an advance from the seat of germination along the back between the two coats of covering, or bran, in which the farina is enclosed. Now, suppose this first disposition and spring of germination be stopped, and that the grain be restored to a dry state; the natural result will be, that vegetation will at once cease, and the vegetation already produced will shrink back, leaving no visible trace that it had been ever brought into action. The question is, would that grain, if sown, ever produce any thing but an abortion? Never: and that abortion would be smut. The natural spring was called into action by moisture; it was afterwards retarded by drought. Nature, in the assertion of her laws, will not be commanded in her processes of reproduction; and when the husbandman will sue to have that grain of wheat restored to its original state, in the hope that new wheat would form it, nature resists the application, and forbids the base grain a participation in the reproduction of its species. We have said that the sound grain will germinate, will produce a sound stem, will blossom fully, and yield its quota of wheat. The other will regerminate, will produce an equally luxuriant stem, shoot forth an ear in the young state perfectly equal to the sound one, but will not blossom nor receive the impregnation of blossom from the ears surrounding it. The result is self-apparent. If it do not manifest in itself, nor receive the impulsive principle of reproduction from its own species, it is plain that it cannot bring forth a reproduction of that species. Yet, the ear is full—of what? Of a *lusus naturæ*—the smut-ball. * * * * * * *

"We would suggest that no man should sow any portion of the present produce of his own farm. A change of seed from a distant district will do more than compensate for the pains and expense of procuring it. The soft, ill-conditioned, and partially sprouted grain is to be avoided. The even, well-shaped, sound, and friable grain is to be chosen. Having selected that, and the ground being ready to be sown, the first essential is, steeping of the seed for about fifteen hours in sea-water and blue-stone. Where sea-water cannot be had, strong brine will answer the purpose. About half a pound of blue-stone, first brayed to powder, and then dissolved in soft water, will be sufficient for a half barrel of brine to steep the first barrel of wheat—a quarter of a pound for the second, and two ounces for the third barrel; adding brine according as evaporation and absorption may have decreased the original half-barrel. When the seed will have been about fifteen or eighteen hours in steep, it is to be removed from the brine, and slacked lime sifted on it freely. When the external moisture has been absorbed by the

lime, the seed may be sown with that confidence which has its rise in the conviction that all that man could do had been effected in the order of reproduction.

"The properties of blue-stone and salt in solution are of so penetrating a nature as to be resisted only by the sound grain. The sickly, or diseased, or otherwise injured grain, does not possess the principle of vegetable life sufficiently active to resist the influence of the solution; and the plain conclusion is, that all the powers of incipient germination are destroyed in the diseased grain, which, when thrown into the ground, will rot, and never shoot forth a stem; consequently, in a field sown with grain thus prepared, we may, generally speaking, look in vain for 'smut.'"

New York Farmers' Club.

At a meeting of the New York Farmers' Club, held on the 5th of August, Dr. Underhill said: "To avoid the fly and the worm in wheat, sow early or late; when your grain has attained some height, you will find the nits of the insects upon it; then turn in sheep or young cattle, who will eat off all the blades, nits and all. If you sow late, you avoid the nits—you may miss them; besides, the manure left by your sheep is very good for your crop. I know but one remedy, which is easily tried, and is said to be effectual. It is quick-lime, slacked perfectly fine; when dried, take it with your three fingers (just as you do grass seed) all over your wheat-field, soon after the wheat is in blossom, and when you see the flies hovering over the field: sow in this way about two pecks of lime on an acre. The dew will moisten the lime, and it then reaches the insect larvæ and kills them. This process has saved a whole wheat crop on one field, while a neighboring one was destroyed by the worm."

From the Maine Farmer.

WEEVIL, OR GRAIN FLY.

Mr. Holmes: Having recently ascertained some facts in regard to the origin of the weevil or grain fly, which may not be generally known, you may communicate them to farmers if you think proper. I have been of the opinion, for several years, that the weevil fly was the insect which is found in the white froth upon the grass at this season of the year. The froth and the weevil made their appearance among us at about the same time. Upon examining the insect in the white froth, just before it comes to maturity, you can see all the features of the fly. In order to be sure that the insect in the froth was the genuine weevil fly, I a few days since cut a number of spears of grass, with the froth and insect upon it, and put them in a tumbler, and covered it with thin gauze, and in a few days I had quite a number of the real genuine weevil fly, as bright and active as you will find them in a few days upon the wheat heads. We may expect a large crop of them this year, as there is more froth upon the grass than I have ever seen before in any season. What it is that deposites the insect upon the grass, is a subject for further investigation.

Respectfully yours,

JOSIAH ORCUTT.

Monmouth, *June* 26, 1845.

Note.—We thank our friend for this account of his experiment. By experiment and observation we obtain much valuable knowledge. We are inclined to think, however, that, on a careful comparison of the two flies, (viz: those from the froth and those on the wheat,) they will be found to be different species.—Editor.

From the American Farmer.

ANOTHER WHEAT INSECT.

An insect has been found the present season in the wheat fields in various parts of the State, which does not correspond with any description that we have met with. It is a white worm, about one-fourth of an inch in length, ribbed, without feet, with two forked black lines upon its head, (shown by the microscope,) and in some instances with a streak of light green extending lengthwise. It is invariably found just above the upper joint, and within the straw. There it feeds upon the inner surface of the straw, abstracting its juices, and preventing their ascent to the head. It was first observed by us when the grain was in the milk, and its presence was denoted by the head having turned white prematurely. Upon examination, the head was found perfectly empty; the straw, like the head, white for several inches down; while below the upper joint it had the thrifty green color of the rest of the field. On opening the stalk, the worm was generally found as before mentioned; in some cases its ravages were seen, but the insect had escaped. In such cases a slight puncture in the straw was commonly perceptible, where it might have made its exit. In one instance nine eggs were found in one straw, and a very minute worm, apparently just hatched from one of them, resembling the insect as found elsewhere, except in size.

With a view of observing the transformations of the insect, we put several wheat stalks, that showed its presence, into a glass jar, with a little dirt in the bottom, for the insect to bury itself in, if such should prove to be its habit, and undergo its transformation. As it increased in age, it became of a yellowish green color, and at length was found slightly mottled with black, and motionless. After the lapse of a fortnight, we observed one morning, on the inside of the jar, a greenish colored fly, about three-sixteenths of an inch in length—being a little shorter than the worm, and of the same color. On the surface of the dirt was observed a cast-off skin, resembling that of the worm.

To be certain that the fly proceeded from the worm, we enclosed several of the pupæ closely in a paper, and, a day or two after, found, upon opening it, the same kind of fly, and the skin whence it issued.

To most farmers with whom we have conversed we find that this insect is, as it was to us, a stranger. We have met with one who says he observed it several years since. With some, the blighting of the wheat-heads passed as the effect of the late frosts. The injury done by it as yet is not serious. Whether it is destined to become another troublesome pest to the wheat-grower, time will determine. If any person can give us information concerning it, we should be glad to have it communicated. Perhaps some of our exchanges can tell us all about it.

From the Boston Cultivator.

SEED WHEAT.

Messrs. Editors: We are told, that in the island of Jersey, (England,) where the farmers sell their *produce* and live upon the *refuse*, it is customary for them to tie their wheat in small sheaves, and by striking each twice or thrice across a barrel while lying on its side on the floor, a superfine sample of wheat is obtained for market; after which the sheaves are thrown by to be clean-threshed, in the evenings of winter, by lamp light.

I have just met with the account of a farmer in Vermont, to whom his neighbors resorted for the purpose of securing seed wheat of superior quality; very fine in appearance, remarkably productive, and of early maturity. He readily commanded three dollars per bushel, when the price of wheat was a dollar and a quarter—calling it the red and genuine *barrel wheat*. But the secret was at last discovered; he used, before threshing his wheat, to select the best sheaves, and, striking them over the side of an empty barrel as it lay on the floor, three or four times before laying them down to be clean-threshed, he obtained in this very simple way a very superior seed-wheat, which the whole county coveted at a double price. Thus the largest and ripest kernels were separated and collected without labor or difficulty, and a profitable business was carried on, until his neighbors discovered how to make "barrel wheat" for themselves.

EDMUND LAWRENCE.

Newark, N. J.

Bloomfield Farm,
New Middletown, Frederick county, Maryland,
January 8, 1846.

Sir: According to the promise I made when I last saw you, I now communicate to you the information I have of the growth and production of wheat, corn, rye, &c. I have been experimenting for a number of years, and have discovered that in all diseases of wheat, rye, &c., there is a first cause, unvarying in its effects; and in order to avoid the disease, we must first find out this first cause, and the proper remedy may then be employed.

In order to improve wheat I select a piece of new land with a north-western aspect; and if I have no new land with such exposure, I take old land lying in the same way and manure it with fresh horse dung, and find it will answer equally as well. You may ask why I select land with this particular exposure to sow my wheat for seed the next year. The reason is this. In the first place a cold hillside renders the wheat more hardy and its color brighter, and when sowed on level land, or southern hillsides, it stands the winter better and ripens six or eight days sooner; consequently it is more likely to escape the mildew and scab, which are known principally to attack late ripening grain, and every year destroy millions of bushels.

In order to prevent smut, after selecting my wheat for seed as above mentioned, letting it get thoroughly ripe before I cut it, I put it up in round shocks, capped with two sheaves butt end up, to secure it from the weather. After threshing it I put it in my granary, sprinkling slacked lime over it at the rate of one peck to ten bushels of wheat. This prevents the wheat from getting into a sweat or heating. It also is an effectual preventive of

the attacks of the weevil, applied either in this way or sprinkled over every layer of sheaves in the stacks or mows. When I am ready to seed my land I prepare my wheat by steeping it in a strong brine of salt and water, that will float an egg, and add to this two pounds of saltpetre and a half pound of blue vitriol (sulphate of copper) to every ten bushels of wheat. After taking it out of the brine I roll it in lime before sowing. The above articles are very cheap, and are in my opinion a certain antidote to smut, and improve wheat in quantity and quality at least ten per cent. The crop from seed thus prepared ripens eight or ten days sooner than wheat sown without any preparation, and consequently is less liable to mildew or scab.

Last year I had 15 different species of wheat growing. Of these I think the following are best adapted to our soil and climate: First, the China. This is a beautiful white wheat, first introduced from the north of China. It produced me this year $47\frac{1}{2}$ bushels per acre. Secondly, the Oregon, brought from Oregon by a missionary in 1839. This year it yielded me 50 bushels and 1 peck per acre. (For a full description of this wheat see the Hon. H. L. Ellsworth's report, as Commissioner of Patents, for the year 1845, page 433.) The "Yorkshire Brown" is a beautiful large, red berry, early in ripening, brought from England, and produced me 37 bushels per acre. "Mount Vernon" is a beautiful wheat, and derives its name from its having been first grown in this country by the illustrious Washington, at that place, many years since. It is believed to be a French wheat, sent over by the friend of Washington and his country, General Lafayette, in 1795. It is an early bald wheat, well adapted to poor land. This year it produced on *poor* land 35 bushels per acre. "May" wheat is very early, and yields well. It ripens before rye, and consequently is not subject to rust or scab. This yielded me $37\frac{1}{2}$ bushels per acre. "Mediterranean" wheat is well adapted to this climate, and grows well on thin lands. Its weight is remarkable. In several instances it has been known to weigh 67 to 68 pounds to the bushel. I sowed this year, for the first time, several very handsome kinds of wheat. The first is from Poland, and called "Polish" wheat. The appearance of this wheat, growing, is splendid. It has almost the appearance of young broom-corn when it first makes its appearance above ground, the stalk is so very strong and coarse; and I am disposed to believe, from the experiment I have made, that it will be well adapted to our climate and soil, and a profitable wheat to sow on thin soils. From the fact of the stalk being so hard and strong, I am induced to believe that it will be impervious to the attack of the fly. It is a white bald grain, heads very large, and the yield great. I have also made an experiment with a wheat called the "Etrurian" wheat. This is from Italy; very large berry, white, and of good appearance. Another Italian wheat that I have, denominated the "Tuscany," can 't be beat in its beautiful form and color. The berry is beautiful—very white; the chaff is white, without awns, or beard, and the growth of the plant closely resembles that of Polish wheat. I am disposed to believe it will suit our section of the country well; and the shape and appearance of the berry will recommend it to the attention of those who are select in their choice of seed. It ripens early, and, before ripening, it casts off its leaves, leaving room for the free circulation of the air and sunshine, and consequently ripens perfectly. This, I think, will always exempt it from danger of mildew or scab.

I have been frequently amused with the speculation of some farmers in relation to the well-known failure of the rye crop in this section of the

country. They exhibit so much ignorance of the nature and instincts of vegetation, that it must be a matter of surprise that men who are brought up to farming, living in the midst of vegetable life, should not be better acquainted with the laws of nature which govern the growth of plants. I wonder how much wheat we could raise here if we had continued sowing the old red-bearded wheat, when it had actually exhausted itself, or run out, as it is commonly termed, in ten years. In consequence of rye being less valuable than wheat, farmers have never taken the pains to change their seed; therefore the rye has degenerated, and become so weakly that it will not bear the severity of our winters; or if it does, and arrives to maturity, the berry is not much better than chess, or cheat, as it is commonly called.

I would recommend them to procure the seed of the large Irish white rye, as the best adapted to their use.

I will now give you a history of the introduction of the Oregon corn, and its characteristics. It was brought to Cincinnati in the winter of 1838, from the southern part of the territory of Oregon, and presented to General Harrison, who cultivated it in the year 1839, and stated that it would produce 30 per cent. more than any other species of corn he ever planted. He was induced to make this statement from the fact that nearly every stalk bore from two to three ears, and from 18 to 24 rows of grains to each ear. This corn has a remarkably thick stalk. Its roots run deeply into the ground, and consequently resist the drought better than any corn I have ever known. The grains are from a half to three quarters of an inch, and in some cases one inch, in length, growing on a very small red cob. Its yield in 1843, from several acres at one end of a field, was 121 bushels to the acre, and shelled seven and one-half bushels to the barrel. (Our common corn only shells five bushels to the barrel.) From this it will be readily acknowledged that it is deserving of the attention and cultivation of every agriculturist desirous of receiving the largest return for his labor, as it yields at least 40 per cent. more than the corn generally planted by the farmers in this section, and is much better adapted to their soils than any kind now in use.

My opinion of the nature of the Hessian fly, and its destructive character, you will see by referring to the report of the Commissioner of Patents for the year 1845, page 433.

I have discovered another steep for wheat, previous to sowing, different from that I spoke of as having used, in the commencement of this letter, which is cheaper and better for that purpose. By subjecting wheat to this process, it will not only be improved in quantity 10 per cent. an acre, but it will cause it to ripen sooner, and change the color of red wheat to white in two years' application. This is a discovery entirely my own, and many persons have advised me to have it patented. I have not the receipt with me at this time, but I will give it to you at some future time, as I consider it too valuable to be withheld from the farmers of our land.

I will send you specimens of my wheat as soon as practicable after harvest, if we both live, and I shall succeed in raising my crops.

I am, sir, very respectfully, your obedient servant,

H. R. SMELTZER.

Hon. Edmund Burke,
Commissioner of Patents.

From the Cultivator.

SPLENDID SAMPLE OF WHEAT.

The recording secretary presented the following letter, with the accompanying sack of wheat:

Sir: I send you, for the State Agricultural Society, a sack of the wheat considered the best grown in old Castile, and sent me lately by a friend in the north of Spain.

The Talavera wheat, already familiar to English and American farmers, is also a Spanish variety. It came originally from Estremadura, a province in the south of old Castile, and of a milder, more uniform climate. The Castilian wheat, it may therefore be inferred, will prove a hardier species.

I have sent to General Rawson Harmon a similar sack, and proposed to him, should its introduction be accomplished under his experienced and enlightened management, to name this variety the *Aguirre wheat*, after D. Macsimo de Aguirre, our excellent consul at Bilboa, to whose good offices I am indebted for the specimens I have received.

General Harmon remitted me last winter, for a friend in France, several varieties grown under his care at Wheatland. Ten kernels taken indiscriminately from these, weighed—

Of white Provence (French)	$8\frac{1}{2}$	grains.
Wheatland red	$5\frac{1}{2}$	"
Virginia May	5	"
Soul's red	5 4-10	"
Soul's white	5 4-10	"
Talavera	7	"
Improved white flint	5	"
The "Aguirre" weighed	$8\frac{1}{2}$	"

A person as little acquainted practically with the tillage of wheat as the writer, would infer, from the above table, that a certain weight of French Provence, white, or "Aguirre wheat," would furnish a greater amount of flour, and less amount of bran, than an equal weight of either of the other varieties.

The bread made from the wheat of old Castile I have never seen surpassed in whiteness. In Spain, as you are perhaps aware, this universal article of consumption is not leavened.

What I send is for distribution, if you think worth while. I will seal up four or five pounds, which might be kept in the room of the Society as a standard whereby to determine the changes the wheat may undergo by culture in America.

Respectfully, yours,

ISAIAH TOWNSEND.

L. Tucker, Esq.,
Rec. Sec'y N. Y. State Ag. Society.

P. S.—I have just had weighed a half-peck of the wheat. The weight was 8 lbs. 9 oz. avoirdupois. This would give $68\frac{1}{2}$ lbs. to the bushel. As this exceeds by $2\frac{1}{2}$ lbs. the heaviest wheat (Hungarian) in Lawson's Museum, (vide his Agriculturist's Manual, p. 14,) I think it wants verifying by a better balance than that I used—the scales of a corner grocery.

I. T.

ALBANY, *November* 24, 1845.

SIR: The wheat of which you speak in your letter of November 18, I received in the course of the summer from a friend, D. Maximo de Aguirre, now or lately our most worthy consul for the port of Bilboa. He describes it as a specimen of "the best wheat of the province of Leon. Similar qualities are raised in La Mancha and Valencia, but none superior."

By reference to a letter addressed by me, with a sample, to the N. Y. S. Agricultural Society, and published in the Cultivator for the month of August, you will find some particulars respecting this variety which may possess for you some interest. In the letter, the wheat was erroneously stated to be of old Castile, instead of the sister province of Leon, and to weigh 68½ lbs. per bushel, instead of 67½, as was determined by more accurate instruments and more care in the trial.

M. Aguirre sent me a fanega of the grain. Of this I have distributed all, except two small sacks of four or five pounds each. It will afford me great pleasure to forward you one of these, which I propose to do in charge of the member from Albany, the Hon. B. R. Wood.

Samples of the wheat have been sown this fall by Judge Lawrence, Bayside, Queens county, Long Island; Messrs. T. Hillhouse, Watervleit, Albany county; M. D. Burnet and P. N. Rust, Syracuse, Onondaga county; Gen. Harmon, Wheatland, Monroe county, N. Y.; and in Virginia and Michigan. Should you wish to ascertain at your office the results of these experiments, you have only to address the gentlemen I have mentioned. General Cass and Mr. Ritchie (of the Union) will inform you to whom you should apply in Michigan and Virginia.

Respectfully, your obedient servant,

ISAIAH TOWNSEND.

Hon. E. BURKE, *&c.*, *&c.*

From an Ohio paper.

HACKLEMAN WHEAT.

Having heard of this wheat, I inquired after its history and qualities. The Brookville American thus answers our interrogatories. We hope, before long, to visit Wayne county, and shall embrace the opportunity to procure some seed. If any of our farmers would like to try this wheat, we will cheerfully aid in getting it for them.

"In our previous notice of the Hackleman wheat we were not sufficiently understood. The wheat known in this neighborhood as the Hackleman (or Alabama) wheat, was introduced here by Judge Hackleman in the year 1836. This was the first that was known of it either in Ohio or Indiana. In the summer of 1836, the Judge was travelling in the south, and being a good practical farmer, who always sees and improves upon everything worthy of his attention, saw a small quantity of wheat different in appearance from the usual crop. He obtained from a woman a small quantity, which he brought home in his saddle bags, and from which all the wheat of this kind in this State and Ohio has been obtained.

"The Hackleman wheat has many qualities which make it superior to any other wheat in this country. It ripens from ten to fifteen days earlier than any other wheat; and consequently has yet never been known to be affected in the least by rust, which so often proves fatal to other wheat. It averages about sixty five pounds to the measured bushel; being, on the average, three pounds heavier than the *red-chaff bearded*, five pounds

heavier than the common, and from five to ten pounds heavier than the *white wheat.* The Hackleman wheat is bald, with the exception of a few long beards on the point of the head; the wheat is rather dark, and flours well.

"This year this wheat did not do as well, probably, as other wheat, it having been injured materially by late frosts after it headed and jointed, from being earlier than other wheat. But in ordinary seasons there has not been this objection.

"Such a demand has there been for this wheat for seed, that little or none found its way to the Cincinnati market until probably last fall, and then in small quantities. For the last year it has been selling here from fifty to a hundred per cent. higher than the common wheat, for seed. Of late, however, we see it has been favorably noticed in the Cincinnati papers.

"Judge Hackleman called it Alabama wheat, although he did not obtain the seed in that State; and it is due that the farmers and millers should call it *Hackleman wheat.* Should distant friends wish it, we believe any quantity can now be had in this region. If it should prove to be no better, it will be well for farmers to sow a part of this kind, as it will ripen sooner, and thereby give farmers a longer wheat harvest."

To the Editor of the American Farmer:

Mr. Editor: Any improvement in the various kinds of wheat is a subject of much importance to the agricultural community generally; and when anything has been effected in this way, it cannot be too generally disseminated.

Many have been the efforts to introduce foreign wheats and assimilate them to our soil, but very few were found to which our climate was congenial. Among the most valuable is the "*Mediterranean.*" The success with which this variety was cultivated induced a search after a better kind, possessing the same advantages, but without its objections, among which is its weakness of straw, causing it invariably to fall on ground of much fertility. It is also a bearded wheat, which is a decided objection, making it very disagreeable to handle, and withal a very dark wheat. But a variety has been introduced by Com. Stewart, called the "*Etrurian,*" which possesses all the advantages of the Mediterranean, and has, besides, a remarkably strong and vigorous stalk. It is quite as early as the Mediterranean, and has a beautiful long, smooth head. The grain is of a superior quality, being round, plump, and white, with a remarkably thin bran.

My attention was attracted to this valuable wheat, a few days since, on the farm of the Rev. Daniel Zollickoffer, near Uniontown, in this county. On inquiry, I found that Mr. Zollickoffer (who, by the by, is one of our most enterprising and successful farmers) had procured it from Com. Stewart's second crop. Mr. Z. has cultivated it two years, consequently full opportunity has been afforded to give it a fair trial; and he assures me that instead of deteriorating, as most foreign wheat generally does, it has improved in every crop that has been grown in this country. I saw it growing beside the Mediterranean—both sown at the same time, about the middle of September, and on ground of the same quality. The Etrurian is equally as forward as the other, and much better headed. It is the richest piece of grain,

I think, I ever saw, and must yield very abundantly, although growing upon ground of but medium quality.

This wheat is not, as its name would indicate, brought from the little island of Etruria, but from Italy. It will very probably, ere long, supersede all other kinds of wheat, as it certainly possesses decided advantages over them. One great recommendation of it is, its being so early as to be in no danger of the rust. It is believed, also, to be fly proof, as no fly, I am informed, has been discovered in it since its introduction into the United States.

From the American Farmer.

THE ETRURIAN WHEAT.

We would call the attention of farmers to the advertisement of Messrs. Boardly & Cox, on our last page, offering for sale a lot of the wheat of a variety termed "Etrurian," noticed in our last as having been raised by Rev. D. Zollickoffer, of Carroll county, Maryland, from seed imported by Commodore Stewart, and raised on his farm in New Jersey. We have full confidence, from what we have learned of this wheat, in its value, and strenuously urge upon our farmers to obtain some of this seed, if ever so small a portion, in order to give it a trial; and as the lot on sale is small, to prevent disappointment no delay should be had in the application, as it will no doubt be speedily disposed of. The peculiarities of this wheat will be found noticed in our July number, and in the advertisement to which we have referred, from information obtained from Mr. Z., who has given us a similar statement when recently in our city. He thinks that on lands suited to the growing of white wheat, it will be found peculiarly valuable.

Since the above was prepared, we have received the following from Mr. Zollickoffer:

LAUDERDALE, *July* 21, 1845.

DEAR SIR: Enclosed you will find a few of the remarkable *beards* or awns of a variety of wheat of which I made mention when I was with you last. This, with several others, I received from H. M. Zollickoffer, of Philadelphia, who received them in a distribution made by the councils of that city of various specimens collected for Girard college. Nearly all of them failed from their late ripening. One variety of spring wheat (labelled Italian) I still retain for further trial. It is a bald or beardless wheat. It is of a compact headed variety, *(triticum compactum,)* and may yet prove valuable. The above long bearded wheat resembles somewhat in its *ear* and *awns* a variety of turgid wheat *(triticum turgidum)* I received four years ago from England, but differs very materially in the form and appearance of the grain. This turgid wheat, with two other varieties, subsequently obtained from Lincolnshire, England, with an expectation of getting a kind that would answer for cold clays, were all given up because of their late ripening. I go in for early wheat; hence my preference for Mediterranean and Etrurian. The Etrurian especially I regard as an important acquisition to the wheat grower. It has also the advantages of the early varieties —escaping rust and smut—and is, to say *the least of it*, as productive as *any* variety I ever grew, and more so than any of the white I ever tried. It has moreover maintained its *color* better than any other white variety I ever tried, as white with me has turned red in one season. But to go back

again to our long-bearded variety. I had given it up, with others. Three heads were found among the Etrurian by my youngest son, and perfectly ripe at the time of cutting that grain. How it got there is more than I can tell. I am disposed now to give it another fair trial. The awns I send you as a mere curiosity. When I get a little more time I want to notice that valuable paper of Mr. Naill's. There has been *too little attention* paid to the proper *time and manner* of putting in our wheat crop. I don't mean, by "too little attention," too little pulverizing the earth. The fact is, in many instances we pulverize too much. In this we follow British husbandry in a case that does not suit our climate, and attribute our failures to anything else other than the real cause.

My son has just measured one piece of ground, on which was grown Etrurian wheat, the product of which we know, having threshed it by itself. The result is about twenty-eight bushels per acre. In this piece there are some twenty large apple trees and a large cherry tree. Any person acquainted with the *condition* of the *ground* would pronounce this a larger produce than could have been expected from any other kind of wheat. I am satisfied that it is five or six bushels per acre more than the Mediterranean grown along side of it, under equal circumstances.

Respectfully yours,
DANIEL ZOLLICKOFFER.

Etrurian wheat.—A few days ago we were politely favored with the following letter, from Capt. G. N. Diehl, of the firm of Diehl & Brother, merchants of this city.—*Philadelphia Saturday Courier.*

PHILADELPHIA, *December* 19, 1845.

GENTLEMEN: Having heard of the superior quality of the Stewart or Etrurian wheat, imported into this country by Commodore Charles Stewart, and of its valuable properties, not possessed by any other wheat I have ever heard of—that of ejecting the Hessian fly, and its non-susceptibility to rust—I was induced, in the fall of 1843, to purchase a small quantity from the commodore, which I sent to a relative of mine near Port Penn, Delaware, with the view of testing its quality and comparative product with that of wheat generally grown in that section. It is perhaps proper to observe (as the character of soil in the State of Delaware varies from the heaviest clay to the lightest sandy) that the soil upon which this wheat was sown is of a *cold clayey nature, and not above mediocrity in quality.* I requested my friend to sow it in the same field with his other wheat, giving it no advantage whatever. This was done; and the yield of the Stewart wheat was at the rate of 32½ bushels to the acre, at the standard of 60 pounds to the bushel; while his other wheat, in the same field, only produced 15 bushels to the acre as the average yield. His entire sowing, in the fall of 1844, was of the Stewart wheat, which also produced 32½ bushels to the acre, at the standard weight, and, if nicely cared for, would have yielded from 33 to 34 bushels.

I think this test sufficiently establishes the superior character (the quality is also most beautiful) of the Stewart wheat. In my opinion, it is the very best seed in the country, as it is adapted to any climate and to any soil. Every farmer should supply himself with this seed, as the advantages pe-

cuniarily would be considerable, and to the country immense. The excess, as per statement above, at the present price of wheat, say $1 30 per bushel, would very nearly pay for the land.

Respectfully yours,

G. W. DIEHL.

From the American Farmer.

MAY WHEAT.

A correspondent at Clear Spring, Washington county, Maryland, writes us (June 4) that his May wheat was already filled, and would be ready to cut in ten days, or perhaps sooner. He considers it superior to any other variety.

L. B. Finley, esq., of the Cubb Hill farm, Harford turnpike, near this city, left with us, about the 1st of June, a stalk of wheat six feet high, which he considered a fair average of a six-acre field. Mr. F. informs us that when he took charge of this farm, several years ago, it was so poverty stricken that the whole farm, of several hundred acres, would scarcely produce grass sufficient for the support of half a dozen head of cattle. He commenced the burning of lime, and with the refuse of his kilns he has brought his farm into a state of tilth which would bear comparison with the boasted farms of Lancaster or Chester county.

From the Genesee Farmer.

CHARCOAL FOR WHEAT.

By all means remember that it is far better to sow but five acres, and so feed the plants that they will give you 40 bushels per acre, than to sow fifteen acres and starve the young wheat plants down to 12 bushels per acre, and have even that badly shrunken with rust. Don't forget that it takes less seed, and fewer hard days' work, to raise 200 bushels on *six*, than on *fifteen* acres of land.

Nothing is more common in western New York, Pennsylvania, and Ohio, than for land to be too rich in vegetable mould to bring good wheat. The straw grows too rank and thick, and is very liable to be affected by rust. To prevent this latter malady, Mr. Haywood, of Buffalo, has used charcoal with signal success. Mr. H. is the owner of a tract of splendid wheat land near Sandusky, Ohio, where he has two flouring mills. He has kindly furnished us with a plot of seven wheat fields, taken for experiments this season, with the results which follow:

No. 1—20 acres; applied fifty bushels of coal, ground fine, per acre; yield 25 bushels per acre.

No. 2—4 acres, no coal applied; wheat badly rusted; yield 5 bushels per acre.

No. 3—15 acres; coal as in No. 1; yield 25 bushels per acre.

No. 4—25 acres; coal as in No. 1; yield 35 bushels per acre.

No. 5—15 acres; coal; yield 25 bushels per acre.

No. 6—8 acres; no coal; yield 5 bushels per acre.

No. 7—6 acres; no coal; yield 3 bushels per acre.

Note.—No. 4 was seeded with *old* wheat.

The soil, culture, &c., were precisely alike, except the use of fifty bushels of coal per acre, as designated—sown in April and May. The soil abounds in lime and organic matter.

Mr. Haywood will apply 10,000 bushels of coal to the fields to be sown in wheat this autumn. It costs him $30 per 1,000 bushels. He grinds it in a common bark mill, used by tanners.

For the Farmer and Mechanic.

CHARCOAL FOR WHEAT AND RYE.

Gentlemen: In fulfilment of my promise, I communicate the following statement of some of the results of my inquiries in relation to the beneficial effects of charcoal as a fertilizer, and as a preventive of shrinkage in winter grain.

Mr. Holloway, of Hancock, Delaware county, informed me that he had heard his father remark that he had never known land to wear out where there had been a coal-pit; but that such places always produced better than the adjoining land. It may be well to remark here, that in some instances I have been told that the burning of a coal-pit had for a while destroyed the fertility on the immediate site of the pit. But this may be owing to excessive burning of the soil, or too great quantity of the coal. We would not expect a crop from seed sown in a heap of lime or silica. Almost all of whom I have inquired confirm the account of Holloway as to its uses as a fertilizer, and its durability. I will state but one of a number of facts proving its benefit in increasing vegetation, besides the luxuriant growth on the sites of coal-pits.

An aged and credible man, Mr. Dow, of Chehocton, in Delaware county, said that some years ago, when living at a place called Butternuts, he purchased a load of charcoal to use in a small furnace. The man who brought it, in passing though a piece of ground, occupied as a garden, upset his load. They gathered up all they could, but much fine coal was left. Mr. Dow and his wife both said that it was astonishing to see the increased vegetation to the extent of where the coal was left. They say it was a moist soil.

These, and a number of facts, the result of much inquiry on the subject, have convinced me that coal can be profitably used as a fertilizer. But it is peculiarly valuable as a preventive of rust and shrinkage in wheat and rye. In proof of which, Colonel Holliday, of Colchester, Delaware county, a reputable man, well esteemed for truth, who was himself a blacksmith, and whose father had followed the same trade, and had burnt many coal-pits, told me that he had made the remark to his father that he had never known grain to be shrunk where there had been a coal pit. Last year, my son-in-law, Henry Woolsey, of Deerpark, in Orange county, said he had a piece of rye much shrunk, and of little value except where there had been a coal-pit, where it was plump and fair. Many other facts have come to my knowledge confirming my opinion that charcoal may be used so as to greatly increase the profits of farming, and particularly where wood is abundant. But as there has, as yet, been little experience on the subject, I would suggest that every farmer who reads this should try the experiment, at least in a small way. Almost any one can procure a little, (if only a bushel;) try it in different proportions; observe the nature of the soil; and, if possible, compare the effect of coal

from different kinds of wood—if those containing more potash are better; and if so, what soils, &c. Some (as the coal from hemlock) contain little or no ash; if such are beneficial, it proves pure carbon to be indeed a manure.

Respectfully yours,

HENRY V. KLEEIT.

From the Mark Lane Express.

EGYPTIAN MUMMY WHEAT.

Mr. Nairne, St. Ford-cottage, Elie, writes to the *Fife Journal*, in reference to some experiments with grains of this wheat. Mrs. Batson, Horseheath, got a return of 1,700 fold; Mr. Whyte, Melville, 2,500 fold. With respect to himself, he says, I dibbled in the seeds myself—a single pickle in each hole; and as the crop got tall, and just as the ears were in bloom, I put aside the netting, and counted the number of ears from each root or pickle in three instances, in each of which there were 14, 22, and 26 ears; and three of the five ears which Mrs. Batson on three occasions sent to me produced 44, 48, and 56 grains; thus averaging 49⅓ grains each—say 50. By multiplying this by the average of the three ears, 20⅔—say 21—we have the result of 1,050 fold. He adds: in the hope and expectation that this new species of "the staff of life," from the banks of the Nile, so celebrated for its fertility, might prove an important acquisition to Scottish agriculture, I sent 202 grains of my last year's crop (I had only 204) to 16 friends, and 4,357 of this year's to 97 friends—in all 4,559 grains to 113 friends—thus averaging 40 grains to each; and my distribution has been into 17 counties, viz: Ayr, Berwick, Bute, Dumfries, Edinburgh, Fife, Forfar, Haddington, Kirkcudbright, Kinross, Lanark, Linlithgow, Perth, Peebles, Roxburgh, Renfrew, and Selkirk.

To the Editor of the Cultivator.

WHEAT CULTURE.

At one of the weekly agricultural meetings held during the past winter, the subject of discussion was the culture of wheat. Mr. McVean, a member of the assembly from Monroe county, made some very interesting and valuable remarks, which, at our request, he has furnished us for publication.

In offering a few remarks (said Mr. McVean) on the cultivation of wheat, I deem it most proper—deferring the minor details of special cultivation, manures, diseases, and different varieties—to introduce the subject by an exposition of the general principles and circumstances of soil, natural adaptation and climate, which will ever control the production of this most important crop.

An examination of the geological map of the State will at once and most readily indicate to the intelligent observer what portions of the State are most naturally adapted to wheat.

First in value, and occupying a large surface, is the Onondaga salt group. The rocks of this group are sometimes denominated the gypseous limestone, or shales; connected with which are the plaster quarries,

the water lime, and the salines of the State. This group, as a whole, embraces the most natural and enduring wheat soil of the State. It includes and extends from Grand island eastward, narrowing to a point in the county of Schoharie. Its soil is composed of diluvial swells, chiefly resulting from and based upon the limestone—a sub-soil susceptible of fertility at any depth, and which, with the substratum of lime rock, is adapted to absorb the superabundant moisture. Hard water, a prevalent growth of oak timber, also upon much of its southern line a comparative absence of vegetable accumulation, and often of timber, consequent upon the annual burning of its natural product, the opening grass, characterize this group. With a surface at once beautiful and accessible, few portions of the State presented a more unpromising *appearance of soil* to the first settler. It's unsurpassed and permanent value has been demonstrated by time and experience, and it is due to the mineral character of its soil, and the fertility and adaptation of the sub-soil.

Although I have dwelt upon this group more at large, because of its natural peculiarities, I am far from claiming for it exclusive natural adaptation to wheat; and only mean to say that it is more generally and permanently adapted than any other, as a whole; that as a whole, it is more certain and enduring, and better resists every unfavorable vicissitude of season, climate, or defective cultivation; and that under continued cultivation, there has been little if any falling off in its annual product of wheat, except when managed with great imprudence.

I am aware that there are large portions of superior wheat soil embraced in the collateral goelogical groups, very much of which is but little if at all inferior to the above in natural adaptation to wheat.

Of these, extending north to lake Ontario, are the Niagara, Clinton, and Medina groups; and towards the south, the Helderberg, Hamilton, and of the Chemung group, more or less of the northern portion, according to the extent of the northern lime drift; for it is an important fact that the diluvial current from the north has conveyed and intermixed beneficially the rock of each of these groups with all the others; conveying the fertilizing lime far south of the actual existence of the rock, in place. These various groups contain collectively a very large portion, perhaps one-fourth, and the most valuable soil of the State.

When the important question arises, where have occurred, and to what causes are due, the evident and conceded diminution of the wheat crop of the State? it will be found that it has occurred chiefly in the last-mentioned groups, and generally in the ratio of their distance from the first; owing, in some instances, to the deficiency of lime, deficient mineral qualities, and excess of vegetable matter and humus in the soil; very frequently to the too level and wet surface; but more specially and injuriously to the tenacity and imperfection of the sub-soil; resisting the escape of the superabundant moisture, whereby large surfaces are often super-saturated with water, inducing winter-kill, debility, and various diseases of the plant, especially under the action of sudden and extreme frost, or heat and drought. Collectively, these results become more manifest and injurious, as the soil has been retained under long continued cultivation, so that only in the most favorable seasons can a full crop be realized in much of these soils; and in these have occurred the principal falling off in the wheat product of the State.

As there are large portions of soil thus circumstanced in the wheat re-

gion of the State, and especially in the last named groups, it follows, if the premises are correct, that in no way can the area of wheat growing be so advantageously extended, in no way can capital and means be so profitably applied, as in improving and adapting these lands, by open and thorough draining, where the mineral qualities of the soil are in other respects proper. It is an indisputable fact, that very large surfaces under cultivation scarcely yield a remunerating return, from the causes here indicated.

In further illustration, and in order to a more comprehensive view of the whole subject, as connected with the above general principles, I desire to remark briefly upon the influence of climate upon the production of wheat, as I am not aware that the importance of the subject is generally appreciated.

Perhaps there is not on earth a better wheat soil than is to be found in New York, so far as the natural capability of the soil is concerned; and yet it is only when the most favorable circumstances of season and temperature combine with a proper condition of the soil that we obtain products approaching those of Great Britain, from lands under no better cultivation, and inferior in natural adaptation to ours. The cause of this is to be found in the excessive character of our climate. Our growing crop has to surmount the extreme severity of our winter, and the more injurious and frequent spring frosts, acting upon a wet surface, producing what is called winter-kill; the succeeding heat and drought acting with sudden change on the same wet surface, upon a plant flourishing only in a dry soil, and naturally incapable of resisting these adverse conditions; and, finally, encountering the excessive heats of summer, (often in connexion with moisture,) stimulating the plant to premature and diseased ripeness. Or, if the foliage is very dense, enfeebling and lodging it, so that the grain is deficient in proportion to the straw. It is a frequent occurrence that the crop is heavier than can be carried to profitable maturity, under the influence of our climate; and practical farmers have long since learned that crops of a medium weight are generally the most profitable.

The influences of climate apply not only to this State, but with more or less injurious force to all the United States, in one extreme or the other of heat or cold; and it is probable, that in the southwestern States of the Union the cultivation of wheat is limited more by the influence of climate than by imperfection of soil.

In accordance with the above principles, and for the reason assigned, it will be always practicable on equal, or even inferior conditions of the soil, to raise heavier crops where the climate is more temperate and uniform; for the reason, in addition to those stated, that the crop occupies the soil a much longer time in arriving at maturity, and it is also less subject to the adverse vicissitudes and influences alluded to. This is believed to be the case in some parts of Europe and in Great Britain, in which last the crop generally occupies the soil in growing state, excluding the fall and winter, from the first of March to the middle of August; but doubtless its insular position has a favorable influence. In such climates, also, it is more practicable, for the same reasons, to carry down the cultivation of wheat to soils of inferior natural adaptation.

As the influence of climate is a fixed condition, and little subject to human agency, our alternative is to adapt our soil to the climate; and this

we may do chiefly by laying the land dry, and obviating on a large extent of our soil the injurious effects of superabundant moisture.

In clearing new land, the importance and economy of retaining, or even planting, at proper intervals, narrow belts of timber, as protection against the winter winds, will engage the attention of practical men. The white oak, which retains its leaves through the winter, is admirably suited for this purpose, and indigenous to the soil.

In continuation, it may be remarked that the winter frost, and heat, and drought of our summers, while offering superior advantages for cultivating and subduing the fallows, affect injuriously at the same time the growing crop, especially in wet and heavy soils; urging their drainage also from the consideration that they are afterwards more easily and seasonably tilled, and more productive of all other crops, as well as wheat.

The additional conclusions resulting from these general views and principles, are, that the first requisite, in the cultivation of wheat, is to obtain a good soil; that a good soil is one that abounds in lime, is clean and dry, and right in the mixture and quality of its mineral matter, including fertility and absorbent qualities of the sub-soil; that a soil containing vegetable fibre or humus in excess produces much straw and little grain, and that consequently alluvial soils are not well adapted to wheat, except when naturally overlaid by a proper mixture of the neighboring upland minerals; that there is much unprofitable application of labor and capital, because of non-conformity to the natural laws of soil and climate; that the cultivation of wheat may be profitably continued or extended on large portions of our land, by adapting the soil to the climate; and thus to the cultivation of wheat, on lands that are too level or wet, provided the mineral qualities of the soil are correct in other respects.

I would finally offer the suggestion to practical men, that, as good wheat lands are well adapted to the production of nutritious pasturage, it will be found most profitable, at the relative prices of products and labor, to renovate the soil to a greater extent than is now practised, by rendering pasturage accessary to the cultivation of wheat in preference to costly or artificial manures, beyond a judicial economy and application of those that accumulate on the farm, and that lands not natural to wheat will be most profitably applied to other crops.

From the Ohio Cultivator.

OHIO WHEAT CROP FOR NEXT YEAR.

We venture to predict, that if no unusual injury befalls the wheat crop now in the ground, the yield of the coming year in this State will be greater than for three years past, if not greater than was ever before produced. Our reasons for this opinion are the following:

1. *The general drought* during the past summer and fall will be found to have had a very beneficial effect on the soil of summer-fallows, not only in destroying the grass and weeds more effectually than usual, but in effecting chemical changes in the elements of the soil, by which means the peculiar food of the wheat plant is rendered more soluble and abundant.

2. The present wheat crop was generally better got in than any preceding one for a number of years past. This, we find, is the testimony of

farmers from all parts of the State. The weather during the fall was remarkably fine for this work, and, in the principal wheat counties, the partial failure of crops gave farmers more time for performing the work well. They also had more land unoccupied, so that a greater number of acres have been sown.

3. Farmers have also been led to bestow more study and attention to the *science* of wheat farming, and to discover the means of increasing the productiveness of their lands. This has led them to adopt a variety of improvements, which will be found greatly beneficial in many cases, and instructive in all. Indeed, we hear from all quarters of the State that the farmers have been trying a multitude of *experiments* in regard to the wheat crop this fall, suggested by the Ohio Cultivator; and when the results of these experiments are published, as they will be in our pages after harvest, next year, the instruction they will impart respecting the culture and improvement of this great staple of Ohio will be worth MILLIONS OF DOLLARS to our readers and to the State.

From the Ohio Cultivator.

EXPERIMENTS IN WHEAT CULTURE.

Benefits of agricultural improvements in Ohio.

The following are some of the experiments and improvements in the cultivation of wheat, to which allusion has been made, and the results of which will be made known through the columns of the Ohio Cultivator after next harvest:

1. *Previous crops.*—Some farmers have sown part of their wheat after summer-fallow, and the rest after frosted wheat, or after oats; others (in the central and southern parts of the State) after corn cut off, and a part among standing corn, with various modes of covering, so as to test the difference as to winter-killing, &c.

2. *In the preparation of land* there have been a great number of improvements adopted, or experiments tried, such as more frequent or extra deep plowing, sub-soiling, under-draining, harrowing, rolling, &c.; also in manuring or enriching the land with lime, ashes, plaster, charcoal, &c. The results of this class of experiments cannot fail to be vastly useful.

3. *New varieties of seed* have been sown to a greater extent than ever before, in nearly all parts of the State. We know of quite a number of farmers who obtained seed from New York and other States, and some have sown as many as from six to ten different varieties for the sake of experiment and comparison. One farmer in this (Franklin) county has sown 150 acres of wheat, consisting of ten varieties—three of these were obtained direct from England, one from France, one from Canada, others from New York and other States of the Union.

4. *Preparation of the seed* with brine, lime, &c., has been practised in a larger number of cases than ever before, and a number of farmers have prepared a part of their seed, and sown the rest without preparation, so as to test the merits of the practice.

5. *The manner of putting in wheat* has been varied more the past fall than ever before, mainly with a view to protect the young plants from winter-killing. Thus some farmers have harrowed in a portion in the usual

way, after sowing on a ploughed surface, and ploughed in other portions, then harrowed a part of the ground smooth, and left another portion rough. Others have *ribbed* the land, as practised by Mr. Noble, of Stark county, so as to have the seed fall in drills, as mentioned in our paper of September 1st, and a few have tried drilling in the seed with a machine constructed for the purpose.

Who can estimate the importance of the instruction that may be derived from all these experiments, when the results are made known, as they will be? And then, too, this is only just the beginning of this great march of improvement. Let the State board of agriculture and the county societies be organized and efficiently sustained, as provided for in the bill now before the general assembly, and such experiments will be multiplied, another year, more than ten fold, and the results will be made known to multitudes of farmers, who cannot be reached by the means now in operation. Who is there so blind as not to see that such improvements in the culture of the staple crops of the State as would be effected by these means would soon increase our surplus products and the revenues of the public works so as to return to the State treasury, many hundred fold, the sum that is asked to be expended in the promotion of these objects? So that instead of the impoverished condition of our State finances being a valid reason for withholding this appropriation, it is, in fact, the greatest reason why the appropriation should be made.

Much might also be said on the benefits that such improvements in agriculture confer on individuals, in the increase of prosperity, and the consequent means of physical, intellectual, and moral progress; but time and space and the patience of our readers forbid any enlargement on these topics at present.

For the Prairie Farmer.

MOWING WHEAT, &c.

BY JAMES M. GOODHUE.

Messrs. Editors: Have any of your readers ever tried the effect of mowing their wheat in the spring? The experiment has been made this season, with such decided success, by some of the farmers in this neighborhood, that I wish you to be informed of the results. Mr. Ashley had a field of winter wheat, growing on the bottom land of the Grant river—a stream much like the Du Page. In the spring, when the wheat had grown to the height of seven or eight inches, and being thickly interspersed with weeds, it was evidently too luxuriant, and threatened to be a mere mass of lodged straw, with heads that would never fill; and, in short, not worth harvesting. He took a scythe and mowed the greater part of the field. The part of the field thus mowed produced a fine crop of clean, straight, well-filled wheat, entirely free from weeds. The remainder of the field, at the same time, was badly lodged, green, rusty—and, in fact, not worth harvesting.

Mr. Reed, of our place, has tried the same experiment with spring wheat; and with similar results.

The advantage resulting from mowing wheat in the spring, I suppose, is principally that you thereby give the light and heat of the sun access to

the earth and to the roots of the plant. It is plain that wheat will thrive best *without a blanket on*, in summer.

Would not mowing also destroy the Hessian fly effectually—that is, the larvæ of the fly, deposited under the leaf?* It might be worth the trial where the Hessian fly prevails.

Mowing wheat, as above mentioned, is nothing new in husbandry; but, I believe, like a great many other useful facts in husbandry, it is new in *our* part of the world. I find reference made to the practice of mowing wheat, in the following extract from "The Comple*at* Body of Husbandry," published in England one hundred years ago; by which extract, it will also appear that the *old chaps* who were then living knew at least the *alphabet* of wheat-growing—and more than could be expected, considering how far they lived from Fox river.

Page 356: "Mr. Yelverton, in 1742, had the prize in Ireland, having six hundred and sixty-eight stone and eleven pounds (153 bushels and 32 hundredths) of wheat off of one acre.† The method he took was to change his seed; then he sowed it not too thick; and he *mowed* it."

After which follows some further account of Mr. Yelverton's method. In fact, by referring to the work above quoted, I find we are in our own day and country only trying over again experiments and methods long since proved and practised in English husbandry.

A few words more, and I will close this hasty communication, already perhaps too long. Mr. Jesse Miles sowed his field of oat stubble, and another of corn stubble, at the same time with winter wheat. The oats that had scattered in harvest sprouted above his wheat, and formed a protection for it through the winter. None of the wheat sowed on the oat stubble was winter killed; while much of that sowed amongst the corn froze out. I have this information from Mr. Miles, who is a man of truth. He believes that if oats are sowed with winter wheat, enough to form an overgrowth, there is no danger of wheat being winter killed.

LANCASTER, *Grant county, Wisconsin, August*, 1845.

For the Prairie Farmer.

HEDGE ROW WHEAT—EARLY SOWING.

BY R. J. CROSS.

MESSRS. EDITORS: The farmers through this section of the country have about finished cutting their grain; much of it, however, is yet in the field, and not secured; but this week, if we continue to have fine weather, will finish stacking or housing nearly all of it. A better quality of wheat, both fall and spring, was never raised on Rock river. In some instances the quantity may have fallen short of the expectations of some; but the berry is as good as could have been anticipated. For spring wheat we are raising here mostly hedge row wheat; the head is quite short, with a long beard, and looks, when growing, much like barley. The grains in the head are quite thick, and are short and plump, and weigh heavy. It is driving out all other kinds of spring wheat from this neighborhood.

---

* The eggs of the fly are deposited on the leaf.

† An Irish acre = $1\frac{5}{8}$ English.

Yourself and correspondents have been continually recommending sowing winter wheat early. Now, I agree with you that wheat should be sowed early, but experience has taught me that it may be sowed too early. I had this season a field of thirty acres of prairie, broken last season. The piece was sowed on shares; I had the centre fifteen acres, leaving five acres on the south of mine, and ten on the north. I sowed the same kind of seed, and limed mine, which was not done by the others. When we came to harvest, I found the east part of mine some four or five days later, shorter straw, and poorer wheat than that on the north or south; but on the west side there was no perceptible difference. I can only account for the difference that that part of mine which was inferior to the other was sown about the 25th of August; that adjoining on three sides the first week in September. Four years ago I observed the same difference in wheat sown in August or early in September. I intend this year to sow from the first to the tenth of September, but not earlier. Spring wheat I do not believe can be sowed too early.

Roscoe, *28th July*, 1845.

There is now and then a season when late spring wheat succeeds better than early. Such a case is, however, an exception.—Editor.

From the Ohio Cultivator.

THE PROPER TIME FOR SOWING WHEAT.

Mr. Bateham: There are, in this section, many different and contradictory opinions respecting the proper time for sowing wheat. A large majority of the best farmers of this latitude concur in the opinion that the best time is from the 15th to the 25th of September; that period being sufficiently late to avoid the depredations of the fly, and likewise early enough to enable the grain to ripen before it will be liable to be attacked by rust.

But there are a few others, intelligent farmers too, who are in favor of sowing about the 1st of September, so as to enable the grain to root deeply and firmly, thereby enabling it the better to withstand the severity of the February and March frosts; arguing, also, that, being sowed thus early, it will have time to outgrow the attacks of the fly. It is further maintained that, by early sowing, the growth will be sufficiently large to admit of its being pastured when the ground is hard frozen in the winter. But, while it is argued by some that wheat, which obtains a heavy growth in the fall, may be fed off without injury in the winter, it is maintained by others that it can never be fed off without serious injury, by producing a feeble growth, "turning the wheat to chess," &c.

Taking into consideration the fact that our meadows have not, on the average, turned off one-fourth their usual quantity of hay this season; and also the fact that the straw off our frozen wheat will not be fit for cattle to eat; and still another important fact, that the best possible pains in saving all our turnips and corn fodder cannot supply the deficiency, it will be very desirable to adopt the plan of early sowing, with reference to winter pasture, if it can be done with safety.

You will confer a particular favor by giving us your opinion respecting these matters.

Yours, &c.,

G. R.

EASTPORT, *Tuscarawas county, Ohio, August*, 1845.

P. S.—Perhaps you can inform us at what particular time in the moon the sowing ought to be done; also the time in the moon for pasturing, so as to render the plan perfectly safe. Please to be especially serious (!) in regard to this matter.

G. R.

Remarks.—In regard to the time of sowing wheat, it is of course impossible to lay down any exact rule that will apply to all parts of this country or this State, with all the diversities of soil and climate, and the differences in respect to the liability to injury from the fly and other casualties. In the north part of this State, and in western New York, from the 10th to the 20th of September is generally considered the most suitable time. In central and southern Ohio, and in other regions of mild climate, the latter part of September or the first week in October is considered the best time. Our own opinion is founded on but slight observations, as yet, in this climate; but, from what we have learned, we are in favor of early sowing, then feeding off with sheep in the fall, if attacked with fly, and at any rate in the latter part of winter, or early in the spring.

As to sowing or pasturing "in the moon," we have no correspondents or subscribers in that satellite as yet, and therefore cannot give any definite information concerning its agriculture!

EXPERIMENTS IN WHEAT CULTURE.

To the Editor of the American Farmer:

SIR: Owing to the drought during the autumn of 1842, the crop of 1843 came forward very irregularly, and ripened in the same manner. That which had vegetated promptly was well matured, that which vegetated later was severely injured by the rust, and that which vegetated during the winter was entirely lost. I had sown my crop a shade later than I otherwise should have done, through fear of an excessive growth during the fall, on account of the *warmth of the earth*—an offence against good husbandry I shall endeavor to avoid as far as possible in the future.

I had observed during the fall that the grain upon the warm exposures about the fields had vegetated more uniformly, and showed a better growth than the surface generally, upon which it was evident much of the seed had not vegetated, notwithstanding the fineness of the weather, until the middle of November, when the weather became unusually cold for that season of the year.

My crop had been sown from the 24th September to the 22d October with the exception of two bushels reserved for an experiment upon the habits of a certain variety of wheat. Fine showers fell on the 18th and 22d, and on the 25th a deeply soaking rain; on the 27th I sowed the two bushels of wheat upon rich potato ground, ploughed just before the rain

on the 25th. It did not vegetate until January, when it came up very beautifully, the thermometer, on the 20th of that month, standing at 67°. About the beginning of February it became very cold, and the ground was deeply frozen in the absence of snow—in March, also, the thermometer sunk to zero; my experiment failed—the wheat entirely perished, which no doubt was the fate of much, if not all, of that portion of the crop which came up in January.

The crop ripened from the 15th to the 25th of July, some three weeks too late. The fate of the crop had certainly depended upon the circumstance of its early vegetation.

The inquiry, could anything have been done which would have promoted the early growth of the crop? presented itself for consideration. How had each field been prepared; in what state of cultivation as to fineness and looseness; what had been manured, and in what manner; what not; when sown, &c.? were all reviewed, and the result appeared to be pretty much as follows: 1. The vegetation of the crop. *First.* That land which had been prepared earliest, whether ploughed once or twice, and had had some rain and was well settled, whether dunged or not, vegetated best; *perhaps because it had retained most moisture, and grew best because it absorbed less of the fall rains, and retained most heat*, as a cloverfield ploughed early and not stirred—merely worked on top. *Second.* Fields that had been stirred or ploughed late stood next; *perhaps, because of their looseness, they were more exposed to loss of moisture by evaporation during the drought, and of their heat through the same medium after the fall rains. Third.* My experiment, although entirely accidental in this connexion, served to show that there was a point of time during the fall after which the crop ceased to vegetate, and during the winter a degree of cold, or other circumstances, which destroyed the plant, not *before*, but *after* it had vegetated.

2. The growth of the crop. That portion of the earlier sown grain which vegetated promptly was considerably in advance of the great bulk of the crop, the whole of which, however, did not improve as much as it was reasonable to expect prior to the commencement of cold weather. From which it would appear that the rain on the 18th and 22d exerted great power in causing the germination of much of the grain sown previously, which, I suppose, was owing to the great quantity of heat then yet remaining in the soil, but considerably reduced by evaporation during and after those rains, and so far reduced by the rain of the 25th as to retard the growth of the whole crop, and entirely prevent the germination of all grain grown subsequently, as certainly was the case in the experiment; which ground being fresh ploughed, gave it the greatest possible capacity to absorb water, which, combining with the remaining heat, passed it off in vapor, and reduced the temperature of the earth below the germinating point, from which it did not recover until the warm weather in January, when the infant plant came forth but to be destroyed by another element of destruction growing out of the great absorbent power of the loose soil—*its expansion when frozen*—which expansion would be in proportion to the quantity of water contained in the soil. The cold in November and December, and in the early part of January, had not destroyed the germ, but the cold in February or March destroyed the plant. If, then, the soil had been ploughed early, had been well settled by rains or the use of the roller, and top dressed (the proper place, I apprehend, for all

fermented manure, instead of stirring in) as far as manured in the fall, and put in with shovel ploughs, cultivators, or harrows, *moisture* sufficient to cause the vegetation of the crop might probably have been retained; and, by proper attention to top-draining, so as to throw the excess of water promptly off the fields during rains after seeding, much heat might have been retained to assist the fall growth, and to prevent injurious expansions by freezing during the winter. I have conformed as nearly as I could to the above view of the subject in sowing the crops of 1844-'45. Oat stubble, well ploughed immediately after removing the crop, top-dressed with manure, harrowed, and left to lie till the time of seeding, and put in with the cultivator, more than quadrupled the product of land of the same field stirred for experiment in the crop of 1844. Owing to the unusual mildness of the last winter, the shade of difference in the present crop is not very great, but very perceptible.

The whole may be summed up thus: That land to be sown in winter grains ought to be *well ploughed when in proper order, and well settled by rain or the roller*, previously to seeding, so as to diminish the absorbent power of the soil; to have the full benefit of which, particular attention ought also to be paid to top-draining, so that the excess of water may pass off of the fields as promptly as possible, whereby heat would be retained to promote the fall growth and protect the plants from injurious expansions during severe weather through the winter, when not covered with snow.

The memory of every practical farmer, I have no doubt, will furnish data to sustain the results. If I am mistaken about the causes, I promise myself the pleasure of being corrected; and as it is an affair of "temperature" pretty much, I promise in advance to keep in the best temper. Different soils may no doubt produce somewhat different results, which gentlemen will please recollect.

The soil upon which the above conclusions were arrived at, would be about as follows:

Silex (sand) coarse and fine, and other insoluble matter	75
Alumine, (clay)	4
Oxide of iron	9
Phosphate of magnesia and lime	0.5
Destructible matter at red heat	9
Humus, soluble in alkali, saline and other matters	2.5
	100

D. W. McNAILL.

COTTAGE FARM, *Sams's Creek, Fred. co., Md., June,* 1845.

PREPARATION FOR SOWING WHEAT.

The following communication from R. T. Underhill, M. D., on the subject of "the preparation of ground and seed for the wheat crop," was read and ordered for publication. It was an interesting practical instruction on that very important subject:

New York, *September* 2, 1845.

My Dear Friend: Being engaged to attend the meeting called for this day in the town of Greenburg, to form a "Farmers' Club" in that town, in accordance with the constitution and by-laws of the Society of Agriculture and Horticulture of Westchester county, I shall not be able to attend the discussions at the New York Farmers' Club on the subjects proposed at the last meeting—"The preparation of the ground and the seed for the wheat crop," &c.

The wheat crop is so valuable, so intimately connected with the prosperity of not only the agricultural, but also the manufacturing, mechanical, and commercial interests of the whole country, that we cannot be too well informed on the subject. Land that has been well manured in a previously cultivated crop, such as corn and potatoes, is, with proper ploughing and harrowing, very suitable for winter wheat. It is always best that the manure should have been applied in the previous crop, particularly if it is rank or recently formed; or your wheat will produce too much straw, be weak, and fall down. There are a few exceptions to this rule. Bone dust, oily fish, street manure, &c., have often been applied at the time of sowing, to secure a good crop. A sandy loam, with a good supply of calcareous earth or lime, forms the best soil for wheat—a certain amount of sand or silex, clay, and lime, being essential to secure a good crop. When I say that the land should be thoroughly ploughed three or four times, and harrowed as often, I am fully aware of what is the usual practice, and also of the loss sustained by only one ploughing and two harrowings. I do not apply these observations to land just cleared from the forest, (though then, the more and better the ploughing, the larger the crop,) or the prairie sod just turned over, but to the land in all the old States, and all lands long under cultivation. The object in ploughing the ground so much, is to turn under more completely atmospheric air, which consists of nitrogen, oxygen, and carbonic acid, a thorough mechanical mixture of which with the soil will insure a great increase of crop; it also acts as a manure. The thorough pulverizing of the soil, so as to make it fine, is secured in this way, which renders it so much better for the fine roots in the early growth of the plant to get well rooted before winter sets in, thus securing it from being winter-killed. This also enables you to pasture your sheep and young cattle upon it in the fore part of November without any fear of pulling it up. They will secure it from the Hessian fly by eating off the larvæ.

It is also very important to prepare the seed properly; you should have the most plump and clean seed that can be obtained. Six shillings or a dollar more per bushel for the best of seed is no consideration, when the advantages are taken into the account. In a barrel or half hogshead make a brine that will bear an egg, from the old salt taken from your meat and fish casks; or, if you have not saved this, ordinary fine or coarse salt, the former dissolving much the soonest, and is generally preferred for that reason. Put in one, two, or three bushels of wheat, and mix well with the brine, and skim off all the chess and other foul seed and light wheat that rises to the top. There should be brine enough to cover the wheat three inches deep. Stir up the wheat with a stick occasionally, and let it remain in the brine three or four hours. Some persons let it remain all night; but I think there is some danger of swelling the grain and acting upon the farina too much by leaving it so long in the brine, and there is

no real necessity for it. Draw off the brine into another cask, and lay the wheat on an oblique surface, so that the brine may draw off; then to every bushel of wheat add three or four quarts of fine air-slacked lime, and rake and shovel it through every part, so that every grain is coated with the lime, and the seed as much separated as possible from each other. (Some good farmers use more lime than the above.) If you have not lime, and cannot readily obtain it, use unleached wood ashes instead. You must measure your wheat before you prepare it, or you will likely, when you sow it, put less seed in than is proper. You will also find it difficult, from the increased bulk, to hold enough each time in the hand. It is, therefore, better to sow twice, and at right angles; that is, take rather less than usual in the hand, and when you have gone over the field, begin and sow it over again in the same direction, (across the first sowing.) You will thus have it more even, and secure sufficient seed, which is rarely the case. When you have taken pains to prepare your land well, use plenty of good seed—a virtue rarely practised in this part of the world. The object gained by the above preparation of the seed is, first, you destroy all the smut, which is a parasitical plant placed on the furzy end of the grain; also all the eggs of insects, that frequently may be seen with a glass on the same part of the grain. The salt and lime also act as a manure to stimulate the germ of the young plant, so as greatly to invigorate it in the early stage of its growth.

Yours, truly,

R. T. UNDERHILL, M. D.

H. Meigs, Esq.,
Secretary N. Y. Farmers' Club.

RAISING WHEAT IN NEW JERSEY.

I will suggest the inquiry whether the culture of wheat might not be improved in this and adjoining counties, where the soil is somewhat wet and clayey, by adopting the Canadian mode of summer tilling; ploughing light the first time, and the second time running the plough one or two inches below the first, and laying the land off into narrow beds or lands—ploughing up and down instead of sideways of any elevation in the ground, and taking care to keep open the furrow between the lands, that the water in fall and spring may be carried off, and not left to stand upon and kill the wheat. This is almost the universal practice in Upper Canada, upon moist clay lands, with a thin soil above the clay, where the farms are more noted for good wheat than in any other part of the province. Their new lands produce better and more wheat after a few ploughings, and several crops have been taken off. The first crop the straw has too rank a growth. E. P.

Essex County, *N. J.*

PROLIFIC WHEAT.

In the harvest of 1840, Mr. C. Spring, of Soham, Cambridgeshire, gathered from one of his fields eighteen very fine ears of wheat, (which were five, six, and seven set) the proceed of which filled a common wine glass. The above was planted the following autumn, and

produced one peck; which was again planted Nov. 3, 1841, and produced seven bushels and one peck; planted the same Nov. 2, 1842, the produce one hundred and eight bushels and two pecks; which was again planted in the autumn of 1843, and produced one thousand eight hundred and sixty-eight bushels. Thus the increase from the eighteen ears, in the short space of *four years*, was the enormous quantity of *four hundred and sixty-seven coombs.*

In March last a blade of wheat sprang up in the garden of a poor man at Shipbourne. It was cultivated, and produced 40 ears of corn, having 2,013 grains. Another blade of wheat, of a different description, also sprang up in the same garden, which produced 26 ears of corn, containing 1,392 grains.—*English paper.*

From the Southern Cultivator.

WHEAT-STRAW A SUBSTITUTE FOR FODDER.

This is the season wheat is got out, and I regret to see the straw is thrown out to make manure. I once had a meadow of thirty acres producing good grass, (feather clover and a broad-leafed blue grass,) all of which made a very fine quality of hay.

To save the trouble of feeding, and to furnish shelter for my cattle, I put forks in the ground, and on them placed poles, of such size and at such a distance apart that the cattle could draw hay.

I stacked wheat straw in the same way, generally on the poorest spots in the field. My cattle were turned in and permitted to feed themselves, and at pleasure to use the stacks as shelter, of which they soon learned the advantages. I found my cattle would use the stacks of hay as shelter, but would not eat any of the hay so long as the straw lasted; which proved to me, if they had proper taste, that the straw was more valuable than the hay.

My horses and mules were furnished with hay alone in the stable, on which they showed health and usual thrift. This experiment for some years was observed, and regularly this preference was shown for the straw by the cattle; and they improved and looked better while enjoying the feed on straw, than when they were confined to hay alone, which was as soon as the straw was consumed.

I have never tried to feed the straw alone to horses, but I would not hesitate to say it is worth more than fodder. Try it; save your own straw; it will feed and sustain cattle, horses, and mules, and ultimately make manure more valuable than by the slovenly process of throwing out to rot.

D. REINHARDT.

GREENVILLE, S. C., *June*, 1845.

APPENDIX No. 3.

From the Cultivator.

EXPERIMENTS IN THE CULTURE OF INDIAN CORN.

Mr. Geddes's experiments.

We are indebted to our friend, George Geddes, esq., of Onondaga county, New York, for the following detailed account of several experiments made by him, with great care, the past season, in the culture of Indian corn. They will be read with interest, and our readers will be glad to learn that these experiments will be continued, with the same exactness, the ensuing season. Mr. Geddes says:

The soil is a deposite of gravel, mixed with sand and clay, resting upon a gypseous shale. The previous course of cultivation has been as follows, viz: In 1837, a crop of corn was raised on a heavy sod turned under that spring, and slightly manured with barn-yard manure. The yield was estimated at 65 bushels to the acre. In 1838, corn was again raised, and without any manure; estimated to yield 50 bushels to the acre. In 1839, it was sown with oats, and yielded a very heavy crop. Grass seed was sown with the oats, which succeeded well. The next four years it was pastured. Plaster was put on both corn crops, and on the oats, and once or twice on the pasture.

The ground was ploughed about the first day of May, six inches deep, and planted on the third and fourth days of that month.

The variety of corn was the improved Dutton—that is, Dutton that had been selected from the earliest ears for a series of years.

Experiment No. 1.—One acre was planted in hills three feet apart each way, six kernels in the hill. Fifty loads of half-rotted manure was put on this acre after it was ploughed, and harrowed in as well as it could be done—it being so coarse that it piled up a great deal before the harrow. The hills had a hoe full of the best of the manure drawn in by the planter, and the corn dropped into it. It was hoed twice, and a cultivator was run once along each row *both ways* at *each hoeing*. The account of the cost of cultivation is as follows, viz:

To ploughing and harrowing one acre - - - -	$1 50
50 loads of manure, drawing, and spreading - -	12 50
2 days' work of one man planting - - - -	1 50
cultivating for both hoeings - - - -	50
hoeing twice, 3 days' work - - - - -	2 25
harvesting, 3½ days' work - - - - -	2 63
	$20 88

The product was 70½ bushels: at 4*s.*=$35 25—$20 88=$14 37 for the use of the land; or the corn cost, besides the use of the land, 29.6 cents per bushel.

Experiment No. 2.—The other acre was cultivated as follows: One-tenth was planted in hills three feet by two apart, six kernels in a hill, and *without any manure.* The account of the cost of cultivation is as follows, reduced to acres:

To ploughing and harrowing one acre	$1 50
planting 2 days	1 50
cultivating	50
hoeing twice, 4½ days	3 37
harvesting, 3 days	2 25
	$9 12

The product was sixty and one quarter bushels to the acre: at 4*s.*=$30 12—$9 12=$21 for the use of the land; or the corn cost, besides the use of the land, 15.1 cents per bushel.

Experiment No. 3.—Another tenth was planted the same distance apart, and the same number of kernels in the hill as the last; and was manured by filling each furrow, as it was ploughed, full of barn-yard manure, *unfermented;* the amount used being at the rate of 150 loads to the acre. The cost of production was as follows, reduced to acres:

To ploughing and harrowing one acre	$1 50
2 men to fill the furrows with manure	1 50
2 days' work planting	1 50
4½ days' hoeing	3 37
cultivating	50
3 days' harvesting	2 25
150 loads of coarse manure	18 75
	$29 37

The product was seventy bushels to the acre: at 4*s.*=$35 00—$29 37=$5 63 for the use of the land; or the corn cost, besides the use of the land, 42 cents per bushel.

Experiment No. 4.—Another tenth was planted the same distance apart, and the same number of kernels in the hill as the last, and manured with coarse manure, in the same way; and had, beside, a top dressing of half-rotted manure, at the rate of twenty-five loads to the acre. The cost of production was as follows, reduced to acres:

To ploughing and harrowing one acre	$1 50
150 loads of coarse manure	18 75
25 loads of fine manure	6 25
2 days' work to put manure in furrows	1 50
2 days' planting	1 50
4½ days' hoeing	3 37
cultivating	50
4 days' harvesting	3 00
	$36 37

The product was eighty bushels to the acre: at 4*s.*=$40 00—$36 37=$3 63 for the use of the land; or the corn cost 45.5 cents per bushel, besides the use of the land.

Experiment No. 5.—Another tenth was planted in drills, three feet apart, the corn four inches apart in the drills. It was manured with 25 loads of half-rotted manure to the acre, put on after the ploughing. The cost of production was as follows, reduced to acres:

To ploughing and harrowing one acre - - - -	$1 50
25 loads of manure - - - - - -	6 25
drilling in seed, 4 days - - - - -	3 00
two hoeings, 3 days' work each - - - -	4 50
cultivating - - - - - - -	50
harvesting (small ears) 4 days - - - -	3 00
	$18 75

The product was fifty-five bushels to the acre: at 4*s.*=$27 50—$18 75=$8 75 for the use of the land; or the corn cost 34 cents per bushel, besides the use of the land.

Experiment No. 6.—The remainder of the ground was planted in hills three feet by two feet, six kernels in the hill, with a top dressing of twenty-five loads of half-rotted manure to the acre. The cost of production was as follows, reduced to acres:

To ploughing and harrowing one acre - - - -	$1 50
25 loads of manure - - - - - -	6 25
2 days' work planting - - - - -	1 50
4½ days' hoeing - - - - - -	3 37
cultivating - - - - - - -	50
3¼ days' harvesting - - - - - -	2 44
	$15 56

The product was sixty-five and one-half bushels to the acre: at 4*s.*=$32 75—$15 56=$17 19 for the use of the land; or the corn cost, besides the use of the land, 23.7 cents per bushel.

It is proper to say, that the cost of labor, for such small parcels, is a difficult thing to determine with perfect accuracy.

The stalks being of such equal value upon each piece, I have supposed it unnecessary to attempt any separate measurement; neither have I kept any separate account of the cost of the seed, for the same reason. The whole was plastered, but the expense being so slight, and costing the same for each piece, no account has been made of it. The manure is charged at its full value in each case, though the land is greatly benefited for future purposes. Hardly a quarter of its cost is justly chargeable to this crop. In No. 2 we have an example in which the effects of the manure are easily traced through many years. The last manuring this piece had was in 1837, and it now produced 60¼ bushels to the acre. No charge being made against it for manure, it appears to be profitable above every other experiment. But if the account could be stated for a period of years for each piece of land, as we have it for this year, I doubt not the manure would be found to pay fully all its cost.

These experiments were made chiefly to determine *how thick* corn should be planted; what is the *most convenient form to place the plants;* and whether the manure should be rotted and applied to the surface, or ploughed under unfermented. The conclusion that now appears likely to be arrived at is, that hills three feet by three feet apart, put in rows, so that a cultivator can be used both ways, is the most convenient form for cultivation, and that six kernels put into each hill will make the corn thick enough. I counted, and made examinations that satisfied me that at

harvest my hills averaged five stalks to the hills; no thinning was done except by insects and accidents. That this is not too thick, is proven by experiment No. 6, where the hills were three feet by two feet, the product being 65½ bushels to the acre, and with one-half the manure that was put on No. 1, which was three feet by three feet apart, and the product only five bushels more to the acre. In fact, I believe that more bushels, with the same manuring, would have been raised with the hills two by three feet, than three by three feet; but the extra labor of planting, hoeing, and harvesting, will more than counterbalance the gain.

The labor required to plough under *unfermented* manure, in any considerable quantity, is so great, and its great bulk, compared with its value, making it so expensive to draw; and the fact that it is not felt until late in the season, and that the next ploughing must be deeper in order to bring it all up and mix it with the soil—are great objections to its use. That the next ploughing must be deeper, in order to bring up all the manure, is evident from the consideration that every time the soil is saturated with water it must sink deeper, unless it is held up by some stratum that is impervious to water. If the contents of the barn-yard are piled up in the spring, as soon as the frost is out, and covered with gypsum, so as to prevent the escape of any of its gases, and turned and re-piled at midsummer, and again covered with gypsum, the seeds of weeds will be destroyed, and the manure will be entirely rotted in time to put on the corn the next spring. The manure used in these experiments was but half-rotted, in consequence of neglecting to return and re-pile it. From the decrease of the bulk, the expense of handling and mixing the manure with the earth will be so much lessened as fully to compensate for all the expense of piling and rotting it.

The cost of the gypsum, too, will be but slight, as but little is required—merely enough to whiten the heap. The corn will then have its stimulus at the time it needs it most; and but few weeds will spring up from the manure. All these considerations lead me to prefer fine manure to coarse.

It is worthy of remark that in No. 2, where no manure was used, the yield was 60¼ bushels; in No. 3, where 150 loads of unfermented manure were used, the yield was 70 bushels—a gain of 9¾ bushels, to be ascribed to the manure; in No. 4, with the like amount of unfermented manure, and 25 loads of fine manure, the product was 80 bushels—a gain of 10 bushels, to be ascribed to the fine manure; showing that one load of fine is worth more than six loads of coarse manure: while No. 6, which was manured with the fine only, yielded 65½ bushels—a gain of 5¼ bushels, to be ascribed to the same amount of fine manure; showing that one load of fine is worth about 3¼ of coarse manure. But the land on which No. 6 was raised was not as rich as Nos. 2, 3, and 4; owing to the fact that it was so situated in the field that it had not been as highly manured in those years gone by, when manure was only drawn out of the barnyard "to get rid of it." Nos. 2, 3, and 4, were nearer the gate, and had been served about alike, and furnish the fairest test of the value of the different kinds of manure.

Some of the results obtained by these experiments were unexpected. The highest yield is very far below the great crops that have been reported. I know not why a hundred or more bushels to the acre were not raised on No. 4, with manure both on top and under the furrow, amount-

ing to 150 loads of coarse and 25 loads of fine to the acre; and that, too, alongside of land that, *without any manure*, yielded more than 60 bushels to the acre.

I purpose, the next year, to plant all of this ground with corn, and carefully measure the product of each piece, with a view of learning the effects of this manuring for the second year.

GEO. GEDDES.

W. C. Young's method.

Mr. Young is a Kentucky farmer, and raised 195 bushels of shelled corn to the acre. When this was first published, it quite staggered the faith of eastern farmers. This roused the zeal of Kentucky, and the Dollar Farmer sets forth the manner; and adds a series of explanations, all of which we give. We must say that such a depth, for seed on stiff soils—on an" soil except the lightest and mellowest, and on these in a cool or rainy spring—would not be proper. Neither could planting be done in March in Indiana, unless in the southern part, and then only in early seasons.—*Ed. Ind. Farm. & Gard.*

That Mr. Young did produce 195 bushels to the acre, we feel just as certain as that we now hold a pen in our hand. It was measured by as respectable gentlemen as any in Jessamine county; gentlemen appointed for the purpose by the Jessamine Agricultural Society. And let it be remembered that this was no first experiment on a single acre. The corn was planted and cultivated according to the method long adopted by Mr. Young, and his whole crop was pronounced equal to the five acres measured. This extraordinary crop was produced in 1840, a year very favorable to corn; but we are told by Mr. Young that in the dryest years he does not get less than 100 bushels to the acre.

"My universal rule is to plough my corn land the fall preceding the spring when I plant; and as early in the spring as possible, I cross-plough as deep as circumstances will permit; and as soon as this is done, I commence checking off: the first way with my large ploughs, and the second with my small ones—the checks three feet by three, admitting of working the land both ways. And then I plant my corn from the 20th to the 25th of March—a rule to which I adhere with scrupulous exactness; planting from 8 to 12 grains in each hill, covering the same from *four to six inches deep*—greatly preferring the latter depth. So soon as my corn is up of sufficient height, I start the large harrow directly over the rows, allowing a horse to walk each side; harrowing the way the corn was planted; and on land prepared as above and harrowed as directed, the hoeing part will be so completely performed by this process, that it will satisfy the most skeptical. Then, allowing the corn thus harrowed to remain a few days, I start my small plough with the bar next the corn; and so nicely will this be done, that when a row is thus ploughed, so completely will the intermediate spaces, hills, &c. be lapped in by the loose earth, occasioned by this system of close ploughing, as to render any other work useless for a time. I thin to four stalks upon a hill, never having to transplant, the second ploughing being performed with the mould-board towards the rows of corn; and so rapid has been the growth of the corn between the first

and second ploughings, that this is performed with ease; and when in this stage I consider my crop safe—my general rule being, never to plough my corn more than four times, and harrow once. My practice is to put a field in corn two successive years, then grass it, and let it lie eight years; a rule from which I never deviate. Now, I do not pretend that the labor bestowed upon a sod-field to put it in a state of thorough cultivation does not meet with a fair equivalent from one crop; but I presume no farmer will doubt when I say the second year's crop from sod land is better than the first, with not more than one-half the labor. The best system of farming is to produce the greatest amount of profit from the smallest amount of labor."

Now, what are the essentials of this method?

First—Fertility of soil, kept up by his system of manuring and grass, of which we shall not speak.

Second—Early planting. In consequence of this, the corn matures before the dry season commences, and every farmer knows that plenty of rain will make a good crop of corn in almost any soil. They all know that the essential thing for corn is rain, and there is generally plenty of rain till about the 1st of July. Mr. Young might plant his corn considerably later, and have it come up as early, and grow off more rapidly, by soaking it in a solution of saltpetre. Thus would the effect of frost and chilly mornings be in a degree avoided; while we feel confident, from our own experience, all injury from the cut-worm would be avoided.

Third—Close planting. Every farmer must know that, to produce the heaviest possible crop, a certain number of stalks must be upon the ground. It is often observed that the great sin of American agriculture is too thin sowing. Grass is nearly always sowed too thin, and the same is true of small grain. In England they sow four and five, and sometimes six bushels of oats to the acre; in this country generally not more than a bushel or a bushel and a half. Hence in England they yield three or four times as heavy as in this country; while in this country we never hear of an extraordinary crop where less than three or four bushels to the acre were sown. Now, we venture to affirm that no very large corn crop was ever grown unless it was planted more than usually thick. In the crop of George W. Williams, of Bourbon county, Kentucky, the corn was planted in rows two feet apart, with a stalk every foot in the rows. This crop produced 167 bushels to the acre. But there is another important advantage of close planting. The corn very soon becomes so dense that the ground is shaded, and the growth of the grass is prevented, and the moisture retained in the soil. By this method of cultivation, no grass is ever allowed to absorb the moisture from the earth, or to take up the nutritious gases which ought to be appropriated exclusively to the corn.

Fourth—Deep planting. This probably operates favorably by giving the roots a bedding where the soil is always moist. Another advantage may be that the roots are thus not so liable to be broken by the plough in cultivation. But it must be here noted, that by Mr. Young's method the corn is "laid by" before the roots are so extended as to be liable to much injury from the plough.

Fifth and last.—It will be observed that, by Mr. Young's method the soil is kept very friable and loose, and that to a considerable depth. This may be considered the all-essential point in husbandry. One of the chief advantages of all manures is, so to divide the soil as to make it that the

atmosphere, from which plants derive their principal nutriment, may freely penetrate to the roots of the plants. In such a loose soil, too, it is well known that much less rain is requisite than in the stiff, cold, close soil. For this reason, gravel, sand, or sawdust, is often the best manure that can be put upon a stiff soil. In the fall of the year, Mr. Young turns down very deep a thick rooted sod of eight years' standing. The vegetable matter in the sod will obviously keep the soil very loose for a year or two by mechanical division, as well as by the slow fermentation of this matter in the soil. But this is not all. The soil is deeply broken up before planting ; it is harrowed thoroughly as soon as the corn comes up, and then there is a rapid succession of ploughing, until the ground is shaded by the corn, and ploughing is no longer possible or necessary. No doubt the plough is preferable to the hand-hoe or cultivator in the case of Mr. Young, for it makes the soil loose to a greater depth ; and we have already explained that, according to his method, the roots of the corn are not exposed to injury from the plough.

From the Cultivator.

Professor Vanuxem's method.

Mr. Tucker : Of all the crops which are raised in the middle States of the Union, none are of so much importance to the farmer as the corn plant, not only for its valuable grain, but its leaves, husks, and stalks, for fodder and manure—no plant which he cultivates being so well adapted to hold the valuable parts of the fæces and urine of the barn-yard, from the pithy structure of its interior.

Corn, for success, requires a loose and rich soil, by which a rapid growth is obtained, and is thus enabled to overcome the changes incident to spring, and its two ordinary and most powerful enemies, the wire-worm and the grub. The ravages of the former are, as we all know, below the surface, and appear to be proportioned to the hardiness and probable poverty of the soil, preying on the main root, effectually preventing all production of the grain, if not destroying the plant. The grub, on the contrary, cuts off the stem near the surface ; its range of destruction more general as regards soil, but evidently feeding from preference upon the more feeble plants ; and therefore, by complying with the conditions requisite for a vigorous growth, its action is but feeble. So, also, when corn is planted upon a sod, recently turned under, the grub finding still its accustomed food.

There is also another observation which I wish to have recorded ; being important to prove, if true, or to set aside, if false. It is the belief that the tendency of the corn plant is to produce a greater yield of grain in northern climates, and less grain and more leaf and stalk in southern ones—no State in the Union producing such prodigious crops per acre as New York, for example. Should this be the fact, it will lead the farmers here, and further south, not to force the plant after it has escaped its early enemies, but to reserve its strength and that of the soil to near the time of setting—merely giving a healthy growth by moderate, and not excessive cultivation, previous to that important state of its being.

For the first years of my farming, the manure was spread in the spring upon a sod for corn, finishing in time to plough for planting. This

plan was changed, hauling out and spreading it the preceding autumn, ploughing as before. This latter method appeared to be preferable, giving not only a quicker growth to the young plants, but evidently a better stand. I also noticed that the effect of the manure from remaining upon the surface for so long a period, comparatively, was to make the soil loose or mellow, and to render the wire-worm and grub no longer causes of uneasiness.

The good effects of covering the ground in the autumn for the corn crop were fully confirmed on an adjoining farm; and the knowledge thus obtained led to the plan which at present I pursue. My neighbor commenced by hauling out the manure which was left after preparing his wheat ground, which sufficed for only about one-third of it. He then proceeded to cover the remainder with straw, but did not finish more than one-half of the part which was left; leaving, therefore, a third part uncovered. The whole was ploughed in the spring in time for planting. It may be satisfactory to state that the field was perfectly level, and the soil of uniform quality throughout its extent, but thin.

From the time the corn appeared above the surface to its perfecting, a marked difference was manifest between the two parts which had been covered and the part left uncovered, having examined the corn at the beginning of the growth of the corn, and at its completion. The parts which had been covered with manure and straw stood well, being unaffected by worms. The color was very good, and produced a fair crop; nor could any difference be perceived between them (as the owner informed me) in the quantity or quality of the grain when husked, so far as the eye could determine.

On the part which had been left without manure or straw, the wire-worm was so destructive as to require more than once replanting. The color indicated less vigor, and the yield in grain inferior in every respect.

No experiment could be more decisive or important as regards the corn-plant than the one related. It established two important facts; the great advantage of covering the ground in the fall of the year for corn; the other, that no difference could be perceived in the crop between the part covered with straw and the part with manure; consequently, that straw could be substituted for manure in its culture.

It has been an object of no small importance with me, in farming, to attain to certainty, quantity, and goodness of crops, with the least expense of labor, and to obtain from the farm all the food or manure required for the various crops to be grown. That the latter object was possible I did not doubt; but in no way could I accomplish it so long as manure was required for both corn and wheat. Had grazing been combined with tillage, there would have been a sufficiency for both these crops; but the farm being wholly arable, there was only enough for one of them.

From being engaged in another pursuit which occupied me some years, and other causes diverting my attention from farming, it is only within eighteen months that I have been able to make an application of straw. My experience, therefore, is too limited to satisfy those who require comparative statistics, but sufficiently so to induce me to believe that I shall attain my object.

The field which was planted with corn last year was a timothy sod, of about three years old. It was covered with straw the preceding fall. The grass at the time of breaking it up, which was just before planting,

looked better than it had at any preceding spring—better than I have known old sods when manured. The corn crop equalled my expectations of it.

The same autumn I also covered four acres of mixed grasses for pasture, leaving about half an acre uncovered by the side of it, which had been in potatoes and highly manured. The grass next year upon the covered part was the best, and better withstood the various spells of dry weather which prevailed last year.

LARDNER VANUXEM.

Bristol, Pa., *January* 6, 1846.

From the Farmers' Cabinet.

GREAT CROP OF CORN.

We, the undersigned, two of the committee appointed by the Chester and Delaware County Agricultural Society on crops, do report: That we have this day viewed the cornfield of Paschall Morris, Allerton farm, near Westchester; that we have calculated the field to contain over ten acres, and that the average yield on the whole field is *a hundred and one bushels and three pecks to the acre.* The corn was planted in hills, $4\frac{1}{2}$ by four feet apart, each way; four grains generally in a hill. The corn was cut up and put into shocks containing six hills each way. Several of these shocks were taken down from different parts of the field, being an average in size, as far as we were able to perceive, and upon being husked, yielded nearly three bushels and a peck of ears each. An average one was shelled in our presence, and yielded one bushel and a half and a pint of shelled corn.

Each shock having occupied 648 square feet of ground; which, being divided into the number of square feet in an acre, will give the number of shocks in an acre: this multiplied by the amount in each shock, will give the result as above stated.

A portion of this field yielded seven half bushels of ears to the shock, which will give an amount of over one hundred and ten bushels to the acre. The committee will further take occasion to observe, that the whole field was remarkably clean and free from weeds, and the soil appeared to be in a mellow and friable condition.

There being no other crop brought to the notice of the committee, it becomes their duty to award to Paschall Morris the premium offered by the society, to which they consider he is fairly entitled.

JOHN WORTH, Jr.
JAMES PAINTER.

11*th month* 3, 1845.

The society requiring, in case of an award of premium for crops, the details of culture, &c., it may be stated that the field was an old green grass sod, not having been ploughed for probably twenty years. Seven years ago it was limed on the surface at the rate of fifty bushels to the acre; since which it has been regularly pastured. It was broken up last spring, with the Prouty plough, to the average depth of about seven inches, harrowed over with the common harrow, and marked out for planting, as stated in the report. The planting was done between the first and

fifth of the fifth month, six grains being dropped into each hill, and afterwards thinned out to four.

When the corn was up two or three inches, each hill received a sprinkle of plaster; no other manure was applied. The after culture was done with the common corn harrow, and one going over with the shovel-plough and the hand-hoe, where the weeds in the hill were too near the corn to be reached by the harrow. Much of the merit of this crop, its freedom from weeds, and continued growth and vigor from the start, are attributable to the deep ploughing and use of the Prouty plough. This plough, by its peculiar mode of operation, breaking the texture of the sod at the same time that it lifts it up and throws it over, pulverizes and crumbles to a certain extent the furrow slice, and by opening it into seams or cracks, admits a passage for the sun and air to the particles of soil, meliorating them, and preparing for the reception of the crop; and when the harrow is afterwards used, the whole is reduced to a finely pulverized state, highly favorable to the action of the atmosphere, and the absorption of its gases, and affording no harbor for weeds, in the shape of hard and impenetrable clods of earth, not uncommon after the use of many other ploughs.

This field, when the ploughing was finished, owing to the open and pulverized appearance of the sod, and the interstices between the furrows being all filled up, allowing no grass or weeds to be seen, resembled one already harrowed, and continued mellow through the season.

PASCHALL MORRIS.

N. Y. Farmers' Club.

The regular topic of discussion was announced—the cultivation of corn—and Dr. Field was called on. He stated that he had made close observations during the four or five years of his farming experience, and had become satisfied that the old system of cultivating corn was decidedly erroneous, although he would not deny that farmers were in the habit of producing very good crops in old times. During his first year he had followed the old system, and he did not obtain so much corn from ten acres as he now got from two. The old way was to begin by ploughing, then to hoe, then plough and hoe again; and this sometimes done three times instead of twice. This, he was fully convinced, was a most injurious practice. In the first place, ploughing disturbed the manure buried with the turf which had been turned over, and permitted the volatile and nourishing gases, the essence as it were of the manure, to escape; and the process of hilling brought the roots too much exposed to the sun, and permitted too much moisture to gather round their extremities. In the next, ploughing cut off a great many of the little roots, which were all important in the process of nutrition. His plan was to first prepare the ground *well*, manure it plentifully, plant the corn in hills about three feet apart and six or eight seeds in each, not forgetting to manure the seed in each hill very powerfully. When it had fairly come up he put in his cultivator—an excellent affair of his own invention—then hoed again; pulled out all but three or four stalks in each hill, and again applied the cultivator—sometimes a third time. He always cut his corn close to the ground.

Dr. Underhill agreed that the cultivator was much better than the plough: too much ploughing and hilling was very injurious. There was no danger of manuring corn too much. He stated that common bog-swamp could be turned into excellent corn land by first draining, cutting down the bogs, and then applying a light coat of four or five inches of sand—silex being a necessary constituent in the production of corn; especially in the stalk, enabling it to stand. From swamp land thus prepared, he had gathered 85 bushels of corn to the acre. As to cutting up corn at the roots, that had long been decided. Judge Buel had discovered, several years ago, that seven or eight per cent. was gained in the grain by this; while the stalks were worth three times the money—six or seven tons of excellent fodder being produced from every acre.—*New York Tribune, June* 16.

From the Albany Cultivator.

INDIAN CORN—NEW VARIETY—PLANTING.

I send you a few ears of a new variety of sweet corn, obtained by the process detailed below:

1*st year*. I had a very early yellow corn, but quite diminutive in its growth—the stalks not over three feet in height, and the ears not over four inches in length. Late in the season I planted this in a patch of sweet or shrivelled corn, then considerably grown. As soon as the tops or blossoms of the yellow corn protruded, they were cut off, in order that the early corn might be impregnated only by the sweet corn. The result this year was yellow corn, of the usual size and appearance.

2*d year*. The last year's product was planted by itself, at a distance from all other corn. The result was, a corn growing about five feet in height, having ears seven to eight inches in length, with a mixture of yellow and white smooth corn and sweet or shrivelled corn on the same cob—fit to eat about the middle of July.

3*d year*. I separated the corn into two parts, the smooth by itself, and the shrivelled by itself, and planted them apart, at a distance from other corn. The product this year corresponded mostly with the corn planted, only there was a slight mixture of the shrivelled upon the smooth corn, and of the smooth upon the shrivelled. The smooth was fit to eat about the middle of July, and the shrivelled about a week later.

4*th year*. I again planted the smooth and the shrivelled corn in separate patches. The smooth was fit to eat 18th July, and the shrivelled the 24th. The height of the stalks averaged about five feet. The character of the two kinds seemed now to be permanently established. The smooth corn produced its like, as did the shrivelled. The latter has the disadvantage of being yellow, but is earlier than common sweet corn, and equally palatable. The smooth corn has a mixture of white and yellow on the same cob.

5*th year*. I separated the white and yellow smooth corn, and planted them apart from each other. The result is two distinct varieties of smooth corn—the earliest fit for eating 19th of July. The white partakes very much of the tenderness of sweet corn. Some portion of it was about a week later than the rest, and grew about a foot higher.

6th year. Having separated the earliest of the white corn from the latest, I planted them apart, and thus procured two distinct varieties of white smooth corn—one fit for boiling 18th July, the other about a week later. Upon the ears of the earliest variety of last year's growth, I noticed a few scattering kernels of white sweet corn. These were carefully picked out and planted this year by themselves. The result is *a white sweet corn, fit for boiling 18th of July*, corresponding with the earliest smooth corn in size of stalk and ear.

My object in instituting this experiment having been to obtain a corn suitable in color and early maturity for marketing, I discarded the yellow varieties, closing the experiment in possession—

1st. Of a white, smooth, eight rowed corn, with ears seven to eight inches long, approaching the common sweet corn in flavor, and fit for boiling 18th of July.

2d. Of a similar corn, but somewhat larger in stalk and ear, and a week later.

3d. Of an *eight-rowed sweet corn*, with ears six to seven inches long, and fit for boiling 18th July, (in 1844, 14th.)

The last variety proving to be the precise article that I was in pursuit of, I have for three years past kept for cultivation that alone. It is that which I send you.

A word upon the proper depth of planting Indian corn. A small patch of the early sweet corn above mentioned was planted last spring *three inches* deep. It came up well and grew thriftily till it was three or four inches high, but then came to a stand. It remained without increasing its height perceptibly, a full fortnight, while another patch of the same kind of corn grew rapidly. On examining the roots of the non-growing corn, it was found that a joint had been formed about an inch and a half above the kernel, and that roots had sprouted out from the joint, *leaving all below to perish.* In other words, the plant had abandoned the lower roots at three inches depth, and formed a new set an inch and a half from the surface. While the process of changing the roots was going on, the plant seems to have ceased to grow above the ground. The effect was to retard the maturity of the corn about a fortnight; but I do not know that its size and productiveness were ultimately impaired.

The inference which I make is, that corn, *to be early*, should not be planted more than an inch and a half deep.

NOYES DARLING.

New Haven, Ct., *November* 18, 1844.

From the New England Farmer.

GREAT YIELD OF CORN-FODDER.

We are indebted to Captain Randall for the following detailed account of his extraordinary crop of corn, a paragraph respecting which was copied into our last from one of the city papers:

New Bedford, *September* 30, 1845.

Mr. Breck—*Dear Sir:* You requested me to give you an account of the product of a field of corn sown broadcast, that you saw when at this

place last summer. I should have done it ere this, but absence from home must be my excuse. Colonel A. D. Hatch—that man of all men for news—has given some account of the crop in the Boston papers. I received a letter last evening from a friend, wishing me to give him all the particulars—the amount of the yield, how the ground was prepared, quantity and kind of seed, &c. And, as I have been getting all the facts together, I will give them to you.

I will first state to you the condition of the land when I took possession of it in March, 1842. There were two acres and about thirty-two rods; it was very full of rocks and small stones, and had been cropped by antique farming, until it would not produce provender sufficient in one year to feed a pair of sheep during that space of time; and such was its condition in July, 1844. At that time, I put it out to clear up and wall by contract; and my specifications provided that every stone that a plough would hit, at a depth of ten inches below the surface, should be removed by men following the plough with iron bars, and that the ground should be grubbed up to the walls to that depth. The contractor ploughed the land one foot deep, harrowed it twice with a heavy jointed harrow, picked up and carted off all the stones, and finished his work as per contract, and to my satisfaction, about the middle of April. I then had the land ploughed across the old furrows by a heavy pair of oxen and one horse, followed by two pairs of oxen on a sub-soil plough, that run on an average 16 inches deep, with men following with iron bars, to remove any stones hit by the sub soil plough. After thus ploughing, the ground was well harrowed by a heavy jointed harrow, the teeth of which are $6\frac{1}{2}$ inches long, and the stones all picked up and carted off. Thirty-five tons of manure were then put on to the acre, and uniformly spread. Said manure was the droppings of 20 head of cows and one horse, all well fed, and the manure was deposited in the barn-cellar, where all the liquid manure was received and well commingled by hogs. This manure was turned under about seven inches, and the ground again well harrowed by the harrow alluded to, and the small stones picked up.

Ten bushels of white flat Maryland corn were then sown broadcast on the piece, and once harrowed as above, and stones again picked up. The cultivator was then run over the ground; it was then bushed with a heavy bush-harrow, and finished by rolling with a roller weighing 2,730 lbs.

I find, by a bill of labor, that the work was finished May 15th. One rod square was carefully measured and cut where it was the smallest, and weighed, by a patent balance, 325 lbs. One rod square, where it was of *middling* quality, weighed 390 lbs. One rod square, where it was of *best* quality, weighed 450 lbs.;—giving an average of 388 lbs. to the rod, and $31\frac{300}{2000}$ tons to the acre.

The corn was cut in the morning by a scythe, and one load carted to a field in the afternoon, where it was eaten by the stock. A load was carried to a small lot near the barn in the afternoon of the same day, and the stock were turned in the following morning after the cows were milked, where the fodder was eaten up clean. In this way it was all fed out green, being a little wilted.

The product of two acres and about thirty-two rods fed *twenty cows in milk, or in calf dry*, one heifer over two years old, two stock bulls, grown, and five spring calves, for seven weeks and five days. This was all the green food my stock had for that time, except what they could pick up

from a pasture burned up, in which they had run during the season. In five days after feeding on corn-fodder, my cows increased their milk one can full, or ten quarts. I did not test the quality of the milk by my lactometer; but I presume it was equally as rich as from grass. I am a pretty good *living lactometer*, as I take about three tumblers full of milk, as a substitute for tea, every day, and I pronounce it as rich from corn-fodder as from grass.

I am satisfied, most fully, that the corn-fodder, taken from $2\frac{32}{160}$ acres was equal to 15 tons of the very best of English hay.

Excuse this tax on your patience, and believe me, dear sir, your obedient servant,

GEO. RANDALL.

APPENDIX No. 4.

From the Cultivator.

THE CULTURE OF THE SWEET POTATO.

The sweet potato (*Convolvulus batatas*) was introduced into England previous to the Irish potato, and was in those days supposed to possess the qualities of restoring decayed vigor to the human frame; and consequently more frequently found in the shop of the confectioner, than in the larder of the cook. It is a native both of Spain and the Canary islands, and was, as an edible, in such *bad repute* that the renowned *Evelyn*, in his work on gardening, as early as the year 1699, recommends that potatoes should be planted in the worst ground. We are glad that we live in an age and country where we can say, plant sweet potatoes in your best land; though in all probability, in the days of the author above quoted, the promise of this root was such that it held forth no inducements to the cultivator; and certainly time has shown that England's climate and soil have proved uncongenial to its improvement. There are many, even in our southern country, at this day, who take his advice, and neglect this crop; from the sole fact, perhaps, that they themselves are not fond of potatoes, not consulting the tastes of voracious hogs and cows, who, squealing and lowing for corn and hay, would be happily regaled with a satisfactory meal from the potato pile.

In the south, we regard the successful cultivation of the sweet potato as an easy attainment. It delights in a sandy, rather light, deep, and well-stirred soil, which must be located on a dry sub soil, though in some instances we have seen good potatoes raised on clay lands. A moist atmosphere, the temperature of which is warm, appears most conducive to the early growth and pleasant flavor of the sweet potato.

From its great use in culinary concerns, it deserves more attention at the hands of our southern planters than it has as yet received. The climate south of 36 degrees has been found admirably adapted to its growth; and no crop can be planted which will yield more to the acre. The fine effect which they give when fed to milch cows, should make it a favorite with all who delight in good milk and butter. When dried in a brick oven, they furnish the material for making a delightful and wholesome beverage in the shape of potato beer. The sweet potato also furnishes a large amount of the vegetable food of slaves in the southern States during the winter months; and though they are generally cultivated as a provision crop by most planters on almost every plantation, the negroes cultivate them in the ground which is allotted to them for their own private use. Such is the partiality of the plantation negroes for potatoes as an article of food, that, as soon as the season for digging arrives, they prefer an allowance of this root to any of the cereal grains. Indeed, it seems they were relished by our revolutionary ancestry; for when an embassy was sent, by the British commander at Charleston, to General Marion, in his swamp encampment, that chivalrous commander, with his characteristic hospitality, invited the royalist to dine with him. The table was arranged; when he found "flesh, fish, and fowl" to consist of sweet potatoes alone. He straightway returned to the British

quarters, and expressed his opinion that it was hopeless to expect to conquer men who could fight for *liberty* on *such fare* as *roasted potatoes.* Mr. John B. White, a talented and gifted son of Carolina, has made this scene the subject of a national painting, which stands high in the world of art. In this picture the negro seems delighted more at the style in which his potatoes were roasted, than at the amazed countenance of the tory officer.

To the negro the potato is a blessing; for, to the known improvidence and carelessness of this race it is particularly adapted, as it requires no culinary skill to make it both edible and palatable, simple roasting in the ashes being the best preparation the cook can give them. It is frequently prepared for the table by baking, and makes good custards, puddings, and pies; the latter equalling rhubarb pies, and made much in the same manner.

If the soil has been exhausted by previous culture, the land should be manured. My father, Mr. John Summer, who has always been successful in the culture of potatoes, observes the rule to manure broadcast; and for this purpose, has prepared in the farm-yard a compost, made by hauling in oak leaves, which, with the admixture of the manure of horses and cattle, furnishes the proper material; and this, when sufficiently rotted, is spread broadcast over the surface of the soil. The general plan, however, in the south, and that which is considered easiest, is to *cow-pen* the ground intended for potatoes, late in the summer. When the latter plan is followed, it should be continued during the early part of the winter, and followed with frequent ploughings, so that the manure deposited may not evaporate, or be washed away by rains. Plough up the land very deep in January, to which we would recommend a sub-soiling to those who have the proper implement. Plough again in February, and in March repeat with a like ploughing; immediately after which bed up the land, with a suitable plough, four feet wide: upon these beds drop the potato slips, six or seven inches apart, covering them with a hoe, one and a half inch deep, with good mellow soil.

It should be remembered that the proper preparation of the soil is of very great importance to the future crop. This mode of planting in beds is usually termed ridging; and simply to cross the beds into equal squares with their width, we can form potato hills by drawing up the corners of the squares with a hoe. We have tried both hills and ridges, and have no preference; though the soil, when planted in hills, is most likely to be washed away by heavy rains. From three to four slips should be planted in the hill. As soon as the slips begin to sprout, the ridges or hills should be scraped off with the hoe, which will enable the young plants to come up readily; and immediately after they have appeared above ground, the beds should be ploughed down carefully, and the ploughing to be performed as close to the plants as they will bear, so as not to disturb the parent slip. This will yield to the young plants that warmth which is so much desired in this culture, and potatoes thus cultivated will stand the summer droughts better than those which have been cultivated otherwise. Frequent ploughings, with a few times hoeing, is all that is necessary, until the vines attain a length which interferes with the ploughing, at which period the ridges and hills should be drawn up with the hoe, fuller than they were originally, and in such a manner that they should be hollow at top. Great care should be taken not to draw any soil on the vines; and therefore, whilst drawing up the beds they should be gently raised by the hands. Just before the vines reach the bottom of the beds, a plough should be run twice through the rows,

in order to give them mellow earth to root in. This will serve to sustain the vines in extreme drought; and as the leaves are almost the only organs which feed tuberous roots, I would earnestly recommend an abandonment of the practice of topping potatoes, or of tearing the vines with a plough, and particularly the practice of making a calf pasture of the potato patch late in summer.

Potatoes for planting should always be raised from cuttings, as they are generally more succulent, and vegetate better in the spring than those which are raised from small potatoes; and hence large potatoes, bringing stouter plants, are preferable to very small slips.

The product per acre may be variously estimated. From two to three hundred bushels are commonly produced. My father has raised upwards of five hundred bushels of good potatoes to the acre, and from two to three hundred bushels has been an average crop with him. They were of the dark mottled variety usually called the Spanish potato, which, for a general crop, we consider best, though any and every sort should be cultivated which are regarded of good quality; and, as there are perhaps more than twenty approved varieties, we are not advocates of any particular one. The yams suit a sandy location, whilst the dark Spanish would succeed better on clay soils. There are several varieties with a red skin, which are much esteemed by some. The variety known as the "Bermuda" are perhaps the best early variety, and for this reason a portion of the crop should be planted of them, or some other favorite early variety. There appears to be only two distinct varieties of the yam, the yellow and white. Both should be cultivated by putting the slips in a bed, and drawing the sprouts as they appear above the ground, and planting them in ridges. In this way, but a comparatively small number of slips are required of this variety. For all other varieties of the sweet potato, we would advise to plant the root itself. The yam is easier preserved during winter, and late in spring is of better flavor than any of the other varieties.

My friend, Colonel R. F. W. Allston, of Georgetown, during the past season, tried an experiment, which, as it is new, and upon the whole has succeeded admirably, I will notice here. The land was laid off in beds four feet apart, and upon these the seed were planted, by laying them on the level ground eight inches apart, and covered over with "tailings," (the straw, &c., blown off in winnowing rice,) to the depth of a foot. In consequence of the severe drought of the past spring, the stand proved a very bad one; the sprouts appearing at the distance of one, two, and three feet apart. The prospect, he says, for a crop, was very meagre until the month of July, when the plants which were standing grew off with a vigor quite remarkable. In consequence of the drought a little earth was drawn upon the beds once, and the grass which showed itself was once picked off. The potatoes were taken up the second week in November, and they yielded 283 bushels of excellent roots to the acre, several of which were exhibited at the anniversary meeting of the State Agricultural Society, weighing from four to six pounds. They were yams.

Our plan for preserving potatoes is simple. A circular bed is formed 8 or 10 feet in diameter; this is raised a foot above the surrounding surface to insure its being dry; on which we place dry pine, straw, cornstalks, or pine bark; in the centre of this we set upright a plank tube, with a great number of holes bored in the sides; around this tube the potatoes are piled up until the cone is completed within a few inches of the top of the tube,

when they are covered up with cornstalks, pine, straw, &c., and lastly with earth five or six inches thick. The tube may be closed in frosty weather by a wisp of straw. During mild weather it should be opened in order to allow the heated air arising from decayed or bruised potatoes to escape. With this, and the addition of a temporary shelter, we have always succeeded in saving potatoes during the winter.

We unhesitatingly recommend that the same land be planted in potatoes each succeeding year, believing that the culture of this crop adapts the soil for the increased reproduction of the root, and that the covering of the vines, when potatoes are gathered, restores to the soil a larger supply of nutrition than is consumed by the production of the crop.

WM. SUMMER.

Pomaria, S. C., *December* 18, 1844.

The sweet potato.—Our planting friends will find in the following article, which we extract from the "Vicksburg Constitutionalist," much valuable information relative to the above named common and useful vegetable:

"We do not know a more valuable edible plant, root, or vegetable, than the sweet potatoe; its productiveness is really astonishing—wonderful. In soil well adapted to its growth, we have *heard* of 1,500 bushels being housed from one acre; we have *known* over 800 saved to the acre repeatedly; and we have evidence of 1,200 bushels being carefully measured from one acre of a field of ten, to decide a bet, many years since. There is no difficulty in keeping them *now* nearly all the year; there is no difficulty or extra labor in the cultivation. Plants are easily saved and kept, and one bushel is quite enough to plant an acre.

"The best soil for sweet potatoes is rich, loose, and *new:* stiff clay does not suit them. *Deep ploughing* is just as necessary as it is for every other agricultural production. Let the beds be made just four feet from the centre of the furrows between; throw the earth up with a heavy plough as high as possible, and then the *hoe* labor will be light; make the ridges eighteen inches high, and do not make them before your plants are nearly ready to set, otherwise they may become soddy or hardened. The plants are often placed immediately in the ridges; this plan may do very well when you have seed in abundance to plant and replant; but we think it best to *bed* the plantings in rich mellow soil, elevated so as to keep the water off, and narrow enough to draw sprouts without trampling them. When they put forth a leaf or two they are ready to place in the ridges, which must be done in rainy or moist weather; and the earlier after there is no danger of frost, the better. In this State the plantings may be bedded in the latter part of February, or any time in March, and the ridges prepared as soon as the sprouts begin to appear handsomely. They must be kept clean to secure a good crop; carefully weeded, and the grass and weeds kept from the whole field. After the vines begin to run, then draw the soil well upon the ridges again; first ploughing carefully between. Sweet potatoes sell readily in all cities, towns, and villages. There is no better food for man or beast. The best of the various descriptions is called, in Mississippi, *yam;* in North Carolina it is well known as the pumpkin Spanish. The medicinal quality is valuable and important. When properly baked,

they are very sweet. Children are very fond of them, and they are a sovereign remedy for the 'summer complaint.' Horses, cattle, sheep, and hogs eat them greedily and fatten upon them. Negroes are always *happy* when they have a plenty of '*sweet taters*'—and negro children never want any thing else. With the least attention properly given, 400 bushels to the acre can be produced; value them at forty cents, (less than they ever have been sold for,) and you have $160 for one acre, which in cotton is not worth over $20. Sweet potatoes cannot be raised north; and our steamboats can find markets up the Ohio, Mississippi, and Missouri, for tens of thousands of bushels."

VESTAL'S METHOD OF CULTIVATING SWEET POTATOES.

Directions for sprouting sweet potatoes.—First: In a bed of earth, make a box by setting boards or planks edgewise on the ground, and put in of good stable manure about a foot in depth, over which spread good rich earth to the depth of two inches; upon this lay the potatoes so near as almost to touch each other, and cover them from two to two and a half inches deep with good loose earth. If the nights are cold, this bed must be carefully and seasonably covered with straw, or some other warm covering, to keep the potatoes from chilling or freezing. Uncover the bed the next morning, or as soon as the weather is warm enough. If at any time the bed become too dry, water it in the evening with branch or rain water; but if well or spring water is used, it should have stood in the sun during the day preceding. The manure put in the box should be horse manure, fresh from the stable, and should not be more than half rotten; for if wholly rotten it will contain no heat, and of course will not warm the bed. There is danger of making the bed too warm, and thereby spoiling the potatoes. To find if the bed be too warm, put your hand into it some distance below the surface. If you find it to be too warm, cool it by watering it. If the manure be kept very wet, it will not heat; nor will it heat if very dry. It ought to be kept moderately moist, in order that the heat may be regular, and of the proper temperature. It may be kept tolerably wet after the plants begin to come up, if the weather is warm. When the plant is three inches high, it will do to set in the ridge or hill.

Directions for planting and raising sweet potatoes.—Put two plants in a hill; set them two or three inches apart, and make the top of the hill sufficiently hollow to hold about a pint of water. Set the plant a little deeper in the hill than it was in the hot bed. Do not wait for rain in order to plant. If the weather be dry, plant them in the evening, and put about a pint of water to each hill; if spring or well water is used, it should have stood in the sun the day preceding, as before remarked. It is better to plant in a dry time and water them, than when the ground is too wet; for when the weather becomes dry, the ground will bake and retard the growth of the plant. The ground should be prepared when it is dry, and the planting done when there is a prospect of rain; but if it should not rain, the plant should be watered. The plants may be planted in ridges; and when they are thus planted, place them from eight to ten inches apart. When planted in hills, put two sprouts in a common sized hill—one is better than three; if the hill is small, one is better than two. When the

patch is large enough, they should be ploughed, for they do the best when thus cultivated. I plough mine each way once, and sometimes oftener. At the first ploughing, I scrape the weeds and grass from the hills and draw a little loose dirt round the plants; draw up but little dirt the first time you work them, for the hills will warm through better when small. When ploughed the last time, hill them up; do this the last of July or first of August. If the vines have grown across the furrows, turn them to the opposite side of the hill; hoe the side thus left bare; then turn them back and hoe the other side; never wind the vines upon the top of the hill—it will prevent the sun from warming it as much as requisite to the full growth of the potato. The vines should not be cut off; if they grow very rank, I pull them loose from the ground and drop them down again; this is to prevent the little sprouts from growing and incumbering the hill with a brood of small stringy potatoes. I prefer this mode to cutting them off. The potatoes are not hurt by a light frost or two; they should be dug as soon as the frost kills the vines, as the growth of the potato will then cease. If dug before much rain they will not be injured.

If any person is desirous of further information respecting the proper culture of the sweet potato, if they will call on me at my residence, I will show them my potato ground, and give all further information. I am aware that the opinion prevails to a very considerable extent that the sweet potato can only be cultivated to advantage in the southern States; but I am satisfied, from thorough observation and experience, that this opinion is erroneous. Any quality of soil that will produce good corn will produce good sweet potatoes; and they will mature in any climate that the common yellow or flint corn will. If the weather will permit, I usually commence planting about the first of May, and I have raised good potatoes from a planting the last of June. The mode of sprouting the potato in a warm bed possesses many advantages over that of planting them in the hill. If the potato is planted in the hill before the earth becomes warmed by the sun, they will rot; and at best, it will take some three or four times the length of time for them to sprout in the hill that it would in the warm bed, and the plant can be ready to transplant from the warm bed to the hill as early as it would do to plant the potato, by which some three or four weeks' (at least) saving of time will be had in the early part of the season, which is a desideratum that is all-important in a climate where the season is short; and furthermore, by this means a peck of seed may be made to plant at least ten times as much ground as it would if originally planted in the hill. Some persons, when they take the plant from the warm bed, cut off a portion of the potato with the plant. This I am satisfied is an improper mode, as the portion of the potato set in the hill with the plant is liable to sprout, thereby producing in the same hill too many plants and of different growths; in consequence of which, a great many small and stringy potatoes are produced, and none of the potatoes will be so large and fine as if the plant alone is set in the hill. The best mode to remove the plants from the warm bed, when they become large enough, is to take the plant between the thumb and finger, close to the ground, pressing on the ground with the other hand so as to prevent the potato from being moved in its bed; then pull the plant directly up: by this means the bed will continue to produce plants for five or six weeks.

It has been contended that sweet potatoes will only grow in sandy ground, but I have proved this opinion to be fallacious. Ground that is

clayey, and even hard, will produce good crops of them, but it should be manured. The best way to manure the ground, after it has been ploughed, and if cloddy harrowed, is to furrow it off as you would to plant corn; then take and put a good shovelful of horse manure in the furrows where they cross, then make your hill over it; it keeps the ground loose and warm, and greatly promotes the growth of the potato. Good crops of potatoes may be raised for a succession of years off of the same piece of ground.

I intend to keep on hand a large quantity of seed, with which I can supply orders from almost any section of the Union. Persons living at any great distance had better procure seed and sprout them at home; but from the last of April to the last of June, I expect to keep on hand, at my residence in Cambridge city, Wayne county, Indiana, a supply of sprouts, or plants, sufficient to supply all demands. They can be sent a hundred miles or more, and grow well. Persons sending for plants should send a box or basket; a half-bushel basket will hold a thousand or more.

In order that the public may be enabled to form some idea as it regards the quantity of potatoes that may be raised on a given piece of ground, I have taken some trouble to have some of my neighbors, to whom I had sold plants, to measure their crops and the ground they grew on. The following certificates will show the result. Before presenting which, however, I would state that I measured the crop of my own raising the present year, and the ground it grew on, and the result showed a yield of *three hundred and ninety-seven bushels* per acre.

Certificates.

Cambridge City, *December* 18, 1844.

This is to certify, that the present year I raised a crop of sweet potatoes from seed procured from Aaron H. Vestal, of this place, which I ascertained, by measuring the ground and crop, to be a yield of *four hundred and eighty bushels* per acre. I raised a crop on the same piece of ground last year, from plants which I procured from Mr. Vestal, that surpassed, both in quantity and in the size of the potato, the present crop. I have raised the sweet potato in the Middle district, in Kentucky, and have seen their crops in both North and South Carolina, but have never raised or seen better potatoes than those above stated.

BENJAMIN BERRY.

Cambridge City, *December* 18, 1844.

This is to certify, that the present year I raised a crop of sweet potatoes, on quite a rough piece of ground, from plants obtained from Aaron H. Vestal, of Cambridge city, which produced a yield of *three hundred and fifteen bushels* to the acre.

JOHN WERKING.

Cambridge City, *December* 18, 1844.

This is to certify, that I raised a crop of sweet potatoes the present year from plants that I obtained from Aaron H. Vestal, of this place. I did not measure the crop, but I should judge that the yield was not short of *three hundred and fifty bushels* per acre. I have seen the best crops of potatoes

that are raised in Maryland, but I have never seen finer ones than those I raised this year. I ate potatoes last April that were kept over winter by Mr. Vestal, that tasted as fresh and sweet as when dug from the hill. I purchased a right from him for keeping potatoes through the winter, and have put up my crop as it directs. So far my potatoes have kept well, and I have no hesitation in saying that Mr. Vestal's mode of cultivating and keeping the sweet potatoe is the best I have ever seen, and one that will prove of great value to community.

WILLIAM CONWELL.

CHARLOTTESVILLE, *Hancock Co., January* 1, 1845.

This is to certify, that I raised sweet potatoes from sprouts procured from A. H. Vestal, of Cambridge city, Indiana, and after measuring the ground and the yield of potatoes, find that the yield was at the rate of *two hundred and ninety bushels per acre.* I also have purchased from him a right to keep sweet potatoes through the winter; and on this day the potatoes are as fresh and as good as when first dug from the ground. I have upwards of one hundred bushels that I am keeping over, and am well pleased with the manner in which they are kept.

HENRY LEHMAN.

From the Indiana Farmer and Gardener.

POTATO CROP.

The potato crop has never been as much attended to in this region as in New York and New England. We believe, however, that its value is becoming apparent, and that potatoes will be produced to a much greater extent than hitherto. Reserving some remarks of our own to a future number, we insert the methods of cultivation employed by eminent cultivators.

Spurrier's method of cultivation.—"Be careful," says he, "to procure some good sets; that is, to pick a quantity of the best kind of potatoes perfectly sound and of a tolerable large size; these are to be prepared for planting by cutting each root into two, three, and more pieces, minding particularly that each piece be furnished with at least one or two eyes, which is sufficient. Being thus prepared, they are to be planted in rows not less than eighteen inches distance; if they are to be ploughed between, they must not be less than three feet, and if four feet apart the more eligible."

"The best method I have found by experience is to make a trench either with the spade or plough, about five inches deep, and putting long dung or straw at the bottom, and laying the sets on it at their proper distances, which is from nine to twelve inches apart, covering them with mould. They must be kept clean from weeds."

Mr. Knight's plan.—"He recommends the planting of whole potatoes, and those only which are of fine medium size—none to be of less weight than four ounces. The early sorts, and, indeed, all which seldom attain a greater height than two feet, are to be planted about four or five inches apart in the rows, centre from centre, the crown ends upwards, the rows to be from two feet six inches to three feet asunder. The late potatoes, which produce a haulm above three feet in height, are to be planted five or six

inches apart, centre from centre, in rows four or five feet asunder. The potatoes to point north and south, and to be well manured."

Makenzie's plan.—" Work the ground until it is completely reduced and free from root weeds. Three ploughings, with frequent harrowings and rollings, are necessary in both cases, before the land is in a suitable condition. When this is accomplished, form the drills; place the manure in the drills, plant above it, reverse the drills for covering it and the seed, then harrow the drills in length.

" It is not advantageous to cut the seed into small slips; for the strength of the stem at the outset depends in direct proportion to the vigor and power of the seed plant. The seed plant, therefore, ought to be large—rarely smaller than the fourth part of the potato; and if the seed is of small size, one-half of the potato may be profitably used. At all events, rather err in giving over-large seed than in making it too small; because, by the first error, no great loss can ever be sustained; whereas, by the other, a feeble and late crop may be the consequence. When the seed is properly cut, it requires from ten to twelve hundred weight of potatoes, from twelve and a half to fifteen bushels, where the rows are at twenty-seven inches distance; but this generally depends greatly upon the size of the potatoes used. If they are large, a greater weight may be required; but the extra quantity will be abundantly repaid by the superiority of the crop, which large seed usually produces. Plant early in May."

Barnum's plan.—" Plough deep and pulverize well by thoroughly harrowing; manure with compost, decomposed vegetables, or barn-yard manure; the latter is preferable. When coarse or raw manure is used, it must be spread and ploughed in immediately. Stiff clay soil should always be ploughed the fall previous. Lay your land in drills twenty-seven inches apart, with a small plough, calculated for turning a deep narrow furrow, running north and south; lay on the bottom of the drills two inches of well rotted barn-yard manure, or its equivalent, then drop your potatoes, if of the common size, or what is more important, that they retain the usual quantity of eyes; if more, they should be cut to prevent too many stalks shooting up together; put a single potato in the drills or trenches ten inches apart; the first should remain uncovered until the second one is deposited, to place them diagonally in the drills, which will afford more space between the potatoes one way than if laid at right angles in the rows. The covering may be performed with a hoe, first hauling in the furrow raised on each side the drill; then carefully take from the centre of the space the soil to finish the covering to the depth of three and a half or four inches. By taking the earth from the centre of the space on either side to the width of three inches, it will leave a drain of six inches in the centre of the space, and a hill of fourteen inches in width gently descending from the drill to the drain; the width and depth of the drill will be sufficient to protect the plant against any injurious effects of a scorching sun or drenching rain. The drains in the centre will at all times be found sufficient to pass off the surplus water.

" When the plant makes its appearance above the surface, the following mixture may be used: for each acre take one bushel of plaster and two bushels good ashes, and sow it broadcast as even as possible. A moist day is preferable for this operation; for want of it, a still evening will do.

" The operation of hilling should be performed *once*, and *once only*, during the season; if repeated after the potato is formed, it will cause young

shoots to spring up, which retards the growth of the potato and diminishes its size. If weeds spring up at any time, they should be kept down by the hand or hoe, which can be done without disturbing the growth of the stalk.

"My manner of *hoeing* or *hilling* is not to haul in the earth from the space between the hills or rows, but to bring on fresh earth sufficient to raise the hill around the plant one and a half or two inches; in a wet season, the lesser quantity will be sufficient; in a dry one, the larger will not be found too much. The substance for this purpose may consist of the scrapings of ditches or filthy streets, or the earth from a barn-yard that requires levelling. Where convenient, it may be taken from swamps, marshes, or the beds and banks of rivers or small sluggish streams at low water. If planted on a clay soil, fresh loam taken at any depth from the surface, even if it partakes largely of fine sand, will be found an excellent top-dressing. If planted on a loamy soil, the earth taken from clay pits, clay, or slaty soil, will answer a valuable purpose; in fact there are but few farms in the country but what may be furnished with some suitable substance for top-dressing, if sought for. The hoeing and hilling may be performed with facility by the aid of a horse and cart, the horse travelling in the centre of a space between the drills, the cart-wheels occupying the two adjoining ones, thereby avoiding any disturbance or injury to the growing plants."

Mr. Barnum's method attracted great attention at the east, from the fact that he actually raised from one thousand to fifteen hundred bushels of potatoes to the acre! When this was first published, it was received with great incredulity; calls were made for the method of cultivation, which drew forth an elaborate article from Mr. B., of which the above is but a morsel. It afterwards was stated, and the most authentic and unquestionable evidence adduced in proof, that Mr. Barnum raised, upon experiment, *at the rate* of more than three thousand bushels to the acre. Now although the labor and the great amount of seed required would prevent the cultivation of many acres of land thus, yet it is worth a trial in a small way; and if one acre can be made to produce one thousand bushels, it will be as much as is usually dug from *five* acres; and it is questionable whether the labor and seed for five acres are not more than that required by Mr. B.'s method for one. [Ed. Ind. Farmer and Gardener.

Mr. A. Robinson's plan.—He says: "If I plant low ground, I plough my ground in beds in a different direction for the water to drain off, then harrow lengthwise of the furrows and small lands. Having a number of them, side and side, I take a light sharp horse-harrow, and harrow crosswise of the beds, which pulverizes the ground and fits it well for planting, leaving a small space between the rows, which answers for two purposes, one for a guide for the rows for dropping: this is done by dropping in the middle of the tracks of the harrow, which is easily and correctly performed by any small boy. It also serves completely to fill up all cracks or holes, the seed lying fair and easy. I then drop my manure directly over the seed potatoes, and when covered up, the seed is safe from inundation, by being some inches above the surrounding surface; the seed lies warm under this manure; the rains drain into the middle furrows. I plant three feet distance. It takes the most of the surface that is pulverized to cover the potatoes; and by the time they are twice well hoed, my hills are as I want them to be. They naturally rise high above the surface in the form of a sugar-loaf; this hill is to turn off heavy rains, and it naturally keeps the potatoes from being too moist, and they are often injured thereby. I

have found that three feet each way is the most proper distance to insure a good crop. I plant three common sized potatoes in the hill; it is no use to cut them; if cut small, the vines come up small and weak, grow fast, and fall down."

The following method we take from an able writer in the Louisville Journal, signing himself GRAZIER:

"The ground selected for potatoes should be dry, where no surface water will rest. It should be rich; if not naturally so, it must be made so by a sufficient quantity of good manure. It should be ploughed twice, and at least twelve inches deep. After the first ploughing, it should be harrowed and *cross* harrowed; and, after the second ploughing, harrowed again; and if not very friable and free from clods, it should then be rolled. The mould cannot be too fine, as on the depth of the ploughing and fineness of the earth depend the *retention of that moisture* so indispensable to the health and maturing of all bulbous roots in particular. The ground thus prepared should then be opened off in *drills*, three feet from the centre of one to the centre of the other, and, if practicable, running north and south. When opened, if manure is to be applied, it must then be hauled in carts. The horse going down between the drills, the bed of the cart will cover two drills, where the manure can be pulled out at intervals, in quantity sufficient not only for the two drills described, but for one on each side in addition; all of which one hand, following with a fork, can easily distribute and spread in the four drills.

"This done, the ground is ready for the seed. I shall first describe the whole of the cultivation and harvesting necessary, and then speak of the seed and its preparation separately. The seed should be dropped in the manure, twelve inches apart; and as quickly as a drill is planted, the plough should follow and cover it in. The double mould-board plough, which is the proper implement for the business, will cover two drills by going once up and once down the field; if the single mould board plough is used, it will of course cover but one drill by the same operation. When your ground is thus gone over, your land will all be in high drills, and can rest so for about one week, when you must take a two-horse harrow, and harrow your drills *across*, leaving your field as level as before your drills were opened. There is no danger, as some would suppose, of disturbing your seed. In a few days, when you can see your plants distinctly above ground, from one end of your drills to the other, you must take your one-horse plough, and go up and down each drill, running the land side of your plough as close to the plant on each side as you safely can, throwing the earth away from it, which operation will leave your field in raised drills between your plants. In a few days after this, you take your double mould-board plough, and go down the centre of the blank drills, covering all your plants nearly out of sight, observing as you go along that the weight of earth is thrown against and not on the plants. Then, in some days after, when your plants are well over the top of your drills, take your scuffle—an implement not unlike your cultivatior in this country, and for which the cultivator can be substituted—and go over your whole field between the drills, giving the earth a good stirring, and not be afraid of encroaching a little at each side on the drill. At this stage, a boy should follow the scuffle, and pull up any weeds that appear on the top or sides of the drills. In a few days after this, when your plants are strong and well up, you go down the centre between the drills, with your double mould-board plough,

the wings well apart, and throw the earth well up to the plants. This must sometimes finish the cultivation, if the vines have spread and are closed too much, but generally the vines will allow it, and the crop be much benefited by one more scuffling; but this time take particular care not to disturb the drill at the bottom, as the bulbs are now forming and spreading; then gently run your double mould-board plough through the whole field again, narrowing the wings of it, which will have the effect of adding the earth, and compressing it to the bottom of the drill, where the bulbs are forming, rather than throwing it up to the stalk at top, where there is sufficient already. This finishes the cultivation.

"To prepare the seed, you must select well shaped, even potatoes, not too small nor too large. Cut them, leaving one good eye at least to every set; prepare them from two to three weeks, at least, before you plant; and each day as you cut, roll your sets in pulverized lime, and spread them on the barn floor to dry; when dry, heap them in a corner till taken out to plant. If this plan is pursued, and the ground selected and prepared as directed, you may rest satisfied that so sure as the laws of nature are invariable, and that like effects follow like causes, as sure will a good and sound crop of potatoes be produced in this climate, with no variation in the result except what may be occasioned by the vicissitudes of the season.

"Ten tons of potatoes, two thousand two hundred and forty pounds to the ton, is considered a fair crop in Ireland. Twelve tons an extra one—equal to three hundred and seventy bushels the first, and four hundred and forty-four bushels the second; allowing sixty pounds to the bushel, which I have found to be about the average weight of a bushel here. I have grown four crops of potatoes in this country, in two different situations and latitudes, (six acres the smallest quantity cultivated any season.) Each crop was treated in every particular as here described, and in three instances out of the four I got a little over four hundred measured bushels to the acre. The fourth crop was only about three hundred and fifty bushels to the acre, caused by the peculiarity of the season, which produced an almost entire failure with my neighbors, under their management."

From the Cultivator of October, 1845.

CULTURE OF THE POTATO IN SCOTLAND.

To the Editor of the Albany Cultivator:

I shall now detail to you the most approved practice in regard to the cultivation of the different crops, and shall devote this letter to that of potatoes, which may be regarded as the commencement of the rotation in the district in which it is reared.

The land, which the previous season had been under oats, is ploughed before the winter frosts set in, with a furrow varying in depth from eight to nine or ten inches. In giving the first furrow for any of the fallow crops, it is considered good practice to cleave down the ridges, taking care, however, to preserve the original furrows, if the land is not thoroughly drained. The advantages of this plan are, the levelling of the field, thus rendering

the subsequent cross ploughing more perfect and more easily accomplished. It also affords greater facilities for the escape of sudden and severe falls of rain on undrained or retentive soils, and more perfectly exposes all parts of the soil to the action of the frost during winter. The land having been ploughed in the manner already described, and that when it is not too much saturated with moisture, the furrows at the headlands and the water courses are cleaned out, so as to prevent any water from lodging.

When the drying winds of March have fairly set in, and the land is relieved of that excess of moisture which usually prevails through the winter, the field is harrowed so as to pulverize the surface, and is then ploughed in a direction across the ridges. This furrow is generally eleven or twelve inches in depth, or as deep as the plough will work. It is then harrowed with four or five turns, and rolled if found necessary; after which, it again receives a double turn of the harrows, and the root weeds which have been brought to the surface, and freed of adhering soil by the different operations, are carefully collected into heaps by bands of women and boys, and removed from the field. Should these various operations not have rendered the soil clean, or of sufficiently fine tilth, it is either grubbed with Finlayson's harrow, or again ploughed, harrowed, and rolled, and the weeds collected as before. If the land has been allowed to become foul, or is of a very stiff nature, it is sometimes ploughed a third time, so as to render the soil very fine and absolutely free from weeds. I have found it an excellent plan, in cleaning foul land, to give it (prior to the spring ploughing) a turn of the Finlayson harrow to the depth of four inches, then to harrow, roll, and collect the weeds brought up. The advantage of this is, that a considerable portion of the weeds are removed before they are mixed through the large quantity of soil stirred by the deep spring furrow; and that portion, too, which being then laid undermost by the plough, is most difficult to be got rid of afterwards. In preparing clay land for green crops, I have tried the following plan with success: As soon as possible in autumn, I plough and otherwise work the land, then open the drills, and allow it to remain in this state till the time of planting. The plough is then passed along the drills, for the purpose of removing any soil which may have fallen from the sides of the ridgelets by the action of the frost; the manure and seed are then deposited, and the ridgelets split by the double-mould plough. A fine "crumb" is thus placed over the manure and seed, excluding the air and drought, and affording a suitable nidus for the young plants; and this in a soil which any amount of labor, by the ordinary method in dry seasons, would hardly reduce finer than a mass of clods the size of road metal. The saving of spring labor effected by this plan is also an important item in its favor.

But to return from these digressions. The field having been properly worked, in the way which I have endeavored to explain, two ploughs, each drawn by two horses, proceed to open the drills, which are usually twenty-seven inches wide. The manure, which has been turned about eight days previously, and allowed to attain a slight degree of fermentation, is then carted out and deposited in heaps, commonly in every fifth drill. A person follows the cart, dividing the heaps equally among them, while five spreaders, with small forks or "grapes," distribute the manure regularly along the drill. These are followed by an equal number of planters with the seed, which they drop seven inches apart. After the ploughs have opened fifteen drills, they return and cover two of those first

opened, in which the manure and seed have been deposited; they then open two in going, and cover two in returning, and so on; thus there are never more than fifteen drills open at once. By the method detailed, the seed and manure are but a very short time exposed to the sun and air, while I am satisfied that there is no plan more economical of labor; for if there are a proper number of men at the dung-hill, not an instant of the time of any individual in the field is lost. Thus, if the dung-hills are conveniently placed, two ploughs, three carts, three men filling manure, one boy driving, and one man dragging out the heaps, in addition to the field workers already mentioned, will finish, in the best style, three Scots acres per day, supposing such were to receive forty tons of manure, about the average quantity allowed. The planting of each field is concluded by working and planting the headlands, cleaning the hedge-roots or bottoms of walls, and planting, by the spade, the corners, as well as all other places not accessible to the ploughs. The beginning of May is as late as it is considered prudent to plant.

The potatoes used for sets or seed, as they are termed, are for the most part brought from some of the high, cold districts, where the land has been lately reclaimed from a state of nature. Those from moss are most esteemed. Peebleshire and the upper ward of Lanarkshire furnish a large portion of those used in Midlothian. As the price generally exceeds the ordinary market rates, while the Lothian farmers themselves do the half of the cartage, the raising of potatoes for seed has of late years added very much to the resources of the farmers in these bleak moorland districts.

Few subjects have attracted more attention in the agricultural world than the cause of the failure of the potato crop, but it still seems hid in impenetrable mystery. It is now a well ascertained fact, that potatoes grown in the potato districts of the Lothians will not reproduce themselves in a healthy manner. I observe in a late number of the "American Agriculturist" what I have heard also stated in this country, that the application of manure in the drill tends to increase the destructive effects of rot. This I must take leave to doubt, as on the only farms in this parish, which have *entirely* escaped this scourge, the manure is never applied in any other manner. It is of the utmost consequence that the seed should not be kept in large heaps, neither before nor after cutting, as fermentation is easily induced, and I am aware has often taken place when little suspected. The quantity of seed used for an acre is four-fifths of a ton.

Soon after planting, the drills are rolled with a light roller; and when the stems are within a short distance of the surface, they are saddle-harrowed. By this means the annual weeds which may have germinated are destroyed, and before another braird can make its appearance the crop is ready for the hoe. Whenever the rows can be distinctly traced, a drill grubber is passed down between them, being adjusted, by means of its screw, to go as close to the young plants as is consistent with their safety. They are then immediately hand-hoed, and in the course of ten days they are again horse and hand-hoed, and slightly moulded with the double mould plough. The growth is now very rapid, and just before the stems from the contiguous drills begin to meet, the grubber is again passed between the rows—this time narrowly set, and drawn by two horses, so as to loosen the soil to as great a depth as possible. They are now finally earthed up; and if the crop is good, the stems soon begin to interlace, and in a week or two present an unbroken surface of leaves and bloom.

Early in October, the crop is raised either with the fork or plough, and stored partly in houses and partly in long conical heaps on the surface of the ground, which are slightly covered with straw, and then with earth to the depth of six or eight inches. The earth for this purpose is obtained by digging a trench along the sides of the heap, thus forming a drain which prevents any water from lodging in the interior. These heaps or "pits," as they are termed, are generally from five to five and a half feet in width, and four feet in height, and are occasionally of great length, containing sometimes 6,000 bushels.

The yield of this crop varies from eight to fourteen tons, but there have been instances of eighteen and twenty tons per Scots acre of marketable potatoes being raised.

In the district around Edinburg, the potato crop is of the first importance. This will be readily understood, when I mention that *here* four contiguous farms have always 200 or 220 acres under it; and as the manure, when brought to the field, does not cost less than 7*s.* per ton, it will be seen that if to this we add rent, seed, and labor, a sum little short of £1,200 is involved in the growth of fifty acres, exclusive altogether of any profit. The price which has been obtained for these two years past was 45*s.* per ton, but some years it has reached 60*s.* and 80*s.* The moderate price of late years has been in a great measure owing to the low price of oatmeal, and a considerable importation from Ireland.

The use of portable manures is gaining ground greatly as an auxiliary to the ordinary manure. Guano on any soil at the rate of three or four cwt. per acre, and rape dust on strong soils, at the rate of six or eight cwt., sown on the drills above the dung, are found to yield a very remunerating profit. Mixtures, containing the elements of the stem and tubers, have also been applied with great success, and as chemistry advances they will no doubt be much more commonly used. As our scientific knowledge becomes more perfect, and more diffused, those unsuccessful attempts at the application of principles to practice will be more rare; and when they do occur, instead of throwing discredit on science, and producing doubt and hesitation, they will be referred to the true cause—the errors or want of knowledge of the operator.

I am, &c. JNO. GIRDWOOD.

FEATHERHALL, MIDLOTHIAN, *August*, 1845.

CULTURE OF POTATOES.

WASHINGTON, D. C., *December* 3, 1845.

DEAR SIR: As requested, and to aid you in your very laudable and praiseworthy undertaking, in disseminating over the country intelligence and improvements in agriculture, I give you my experience and observations on the subject of the round or Irish potato, being fully satisfied that for many years the demand for them would increase, and their importance for the use of man be more fully demonstrated; under such impressions, I turned my attention to the culture and best manner of preserving them for family use and for transplanting.

1st. I have formed a clay soil, well manured from the cow pen or horse-stable, in October or November, and ploughed in immediately from four to eight inches deep, (a cow pen or horse-lot, ploughed in the spring, where

cows, hogs, and horses have been penned during the season, and again ploughed in the fall, and lay over to be mellowed by the frost, is better;) to lay over until spring, then prepared, at the season for planting, in drills three feet apart. Have a compost prepared of leached ashes, burnt earth, chaff, or short straw, and scatter in the drill, on which drop your potato. Small or middle-sized potatoes should not be cut, and large potatoes not more than once, (making two pieces,) commencing to cut at the stem end, and cutting them lengthwise. The potato should not be covered deep; and in dressing them, no additional earth should be drawn about the stalk after it is above the ground. They should be kept clear of weeds or grass by hand-weeding, if necessary.

If your potato field be properly prepared before planting, but little labor is required for their cultivation—the less the better.

So soon as your potatoes are ripe, (which may be known by the dying of the vines or stalks,) have them taken up in dry weather, and put into boxes or barrels, in dry sand, which must be clear of any vegetable matter or earthy substance. Have your boxes or barrels then placed in some cool place, that is dry and airy, until winter or very cold weather; then remove them to a dry cellar, or other place, not too warm. Thus stored, they will keep a year without sprouting; when taken out for use, they will be found full, mealy, and the flavor much improved—retaining all their original fullness.

When planted, after being preserved in this way, they give nourishment to the young plant, and aid greatly in bringing forth good healthy new potatoes. Great care should be taken, when harvesting the potatoes, to select none but the best and ripest for seed and family use—the small and unripe should be selected for the use of the stock.

The round potatoes are better and more profitable in high latitudes, and north of the thirty-sixth degree of north latitude in North America; south of that they degenerate after the first year. Seed taken from the north to the south does well for early potatoes the first season, but will not do for transplanting.

It is important that the growers of the potato, who desire a continuance of healthy, sound potatoes, should look to their potato vines or stalks, and when the balls are fully ripe on the stalks, (which will be known by the stalks dying,) gather them, wash the seed in clear water, and place them to dry, secure from insects; when dry, put them in a dry place until spring. Have prepared a bed in the garden, and put the seed in drills eighteen inches apart; cover them with earth well pulverized, not deep. Keep the weeds and grass from about the young stalks. They will show the time for gathering by the dying of the vine; then take them up and place them in clean sand until the next spring; then plant them in good soil with compost, as directed in the first part of this communication. When you take them up, you will discover perhaps a dozen varieties and colors. You should now assort them, and put each kind to itself, in sand. They do not come to perfection for use until the third year. Plant each kind by itself, not together, the third year, as directed, and you will discover, when you take them up, the potatoes that will be most productive, and useful for family purposes; which may be preserved for use and planting. Those less productive may be tried on other soils, and prove good. This done, and pursuing the directions herewith, your potatoes will continue perfect many years. You will hear of no failures of crops, or diseased potatoes. Laziness and want of at-

tention to the proper culture of this invaluable vegetable are the causes of failure.

I never had a failure of crop; always plenty, and good, for myself and neighbors. Nothing but adversity and a scourge on man will make him show his energies: it is necessary, or the great Author of all good would not send it upon us.

Your friend,

JNO. A. ROGERS.

Hon. EDMUND BURKE,
Commissioner of Patents, Washington, D. C.

From the New England Farmer.

CULTURE OF POTATOES.

S. Widney, of Piqua, Ohio, successfully cultivates potatoes on the following plan: Plant in hills, and when the potatoes are about an inch out of the ground, take a light plough and run it so close to them as to cover them lightly with earth. When they get through this an inch or so, cross plough them, covering up as before. This mode is stated to be equal to the best hoeing, besides being a great saving of labor. Mr. W. states that he has practised this mode for several years, and has never lost a hill or had them at all injured by covering.

From the New England Farmer.

CULTIVATION OF POTATOES.

Mr. BRECK—*Dear Sir:* I observed in the last number of the Farmer an account of the plan by which Mr. Widney, of Ohio, successfully cultivated his potatoes. It augurs well when even one person has the fortitude to step beyond the barriers of any ancient system, which may have nothing to recommend it but its antiquity; and it must be no small degree of pleasure to such person if his plan proves successful; for besides the pecuniary advantage to himself, it saves him from the ridicule of the friends of "the good old way," and they are neither few nor far between.

In reading Mr. W.'s account, a thought suggested itself to my mind to give you an account of a plan which I have practised with success; but I am not the patentee, nor do I know to whom the honor of originating it belongs. All I know is, that it was the common mode of cultivating potatoes in Scotland twenty years ago, and I did not learn that it was *new* at that time.

The plan is as follows: After the ground is properly prepared for planting, furrows or trenches, or whatever you please to call them, are opened with the plough, into which the manure is put, and the potatoes planted either whole or cut. If cut, they may be planted from 4 to 10 or 12 inches apart in the furrow; if whole, from 12 to 18 inches apart. The distance should vary according to the fertility of the soil and the quantity and quality of the manure used, and also according to the kind of potato and the purposes for which they are intended to be raised. The distance between

the furrows or drills (as they are called) should not be less than 30 inches. After the potatoes are planted, they are covered with the plough, and in a dry season it is a good plan to roll the drills, in order to prevent the moisture from escaping; but in a wet season rolling should be omitted. By compressing the earth about the seed it vegetates quicker, a thing of the utmost importance in the present diseased state of the potato plant. If any doubts are entertained of the vegetative powers of the seed, it should be planted when the land is in a moist state. In very dry weather the morning and the evening is the best time; or if a damp day occurs, it should be taken advantage of for that purpose, and in all cases the seed should be covered immediately after planting; for a potato with weak powers of vegetation, when planted under such circumstances, and on well fermented manure, will grow well, when the same potato, if planted in dry weather, and on unfermented manure, and exposed for some time to the influence of a hot sun, would rot before it would vegetate. And that is perhaps one reason why one portion of seed grows well, while another portion, in every respect the same, does not vegetate at all, or comes up so weak that the plants are entirely useless for producing a crop. (Exposing potatoes to the sun for a few weeks in the fall has a good effect in producing quick and powerful vegetation in spring. I have tried the experiment with perfect success.) When the potato plants are about an inch above ground, the plough is run along the drills or ridges, and the plants are covered in the way that Mr. Widney speaks of; and the deeper they are covered the better. After this operation is performed, a light harrow is passed over them; but care should be taken to keep it moving lightly, by having the two ends of a rope fastened to the hind bar of the harrow, the ends of the rope being far enough to enable the person who attends it (he having the bend of the rope in his hand) to lift the harrow all off the ground at once, when it meets with any obstruction or becomes filled with weeds or any other material. I prefer a harrow so light, and the teeth so fine, as will allow of its being passed over them two or three times, as that will leave the ground in a more pulverized state, and the weeds (if any) will be better shaken and more exposed to the sun than if a heavy harrow had passed over only once. It should never be allowed to drag, but should be kept playing lightly on the surface of the drills or ridges; and, by using double reins on the horse, one person can easily manage both the horse and the harrow. The best kind of harrow for the purpose is one with curved bars, (after the form of the felloe of a cart-wheel,) with the teeth longer where they enter the side of the drill, near the bottom, than those which enter it on the top. After this operation has been properly performed, the ground is left in a fine pulverized state, and as clear of weeds as when the potatoes were planted.

When potatoes are early planted, and weeds begin to show themselves at an earlier period than that mentioned above, the operation should be performed twice; but if it requires to be performed only once, I should defer it until the plants are above ground, as by so doing the weeds are destroyed, and before they can start again the potato tops will cover the ground, and the weeds will therefore only have a sickly growth.

After the plants are three or four inches high, a small plough (a light sub-soil plough answers best) should be run as near as possible to the plants, and the earth thrown from them. If a sub-soil plough, or any plough without a mould, is used, (which are the kinds best adapted for the purpose; for if the plough has a mould it cannot be let in deep, as it would throw the

earth on the opposite row,) it should be let in as deep as possible, both on account of the present and after crops. If the ground has been suffering by drought about the time the potatoes are in this stage of their growth, I should prefer having them lying in the state last described just at the time the rain fell, as the moisture would get immediately to their roots; and if the earth is laid up to the plants in a damp state, it will retain the moisture about the roots for a considerable time, especially as the tops will shade the ground, and to a certain extent prevent evaporation.

After the earth has been thrown away from the plant, the cultivator should be run in the space between the rows, to level the ground and to shake and expose the weeds. After this operation has been performed, the plough should be run along the centre of the space between the rows of plants, and the finely pulverized earth laid up to them; but care should be taken to keep the drill or ridge flat and wide on the top, for the purpose of receiving the moisture of dews and rains. When the potatoes are further advanced, the plough may be run through the same tract as before. It may not be necessary to lay up any earth this time, but only to renew the surface of that which has been previously laid up, in order that any weeds which were making their appearance might be destroyed, and also that, by breaking the crust, which had become hard on the surface, evaporation and absorption will go on more freely; and it may even be necessary to run the plough through a third time, for the above reasons.

The above system is as applicable to the cultivation of potatoes planted in hills as to those planted in drills, rows, or ridges, or whatever you may please to call them. The plough can be run at right angles in the spaces between the hills, as practised by Mr. Widney.

The plan I have described is not so simple and easily comprehended or practised as that of Mr. W., and is therefore not so likely to be adopted; but those who have fortitude enough to leave the ancient land of *hoe-field* and travel as far as Mr. W.'s system, and find it successful, may perhaps screw up courage enough to proceed a few steps further into the depths and mysteries of cultivation, and perhaps find out a plan far surpassing any that has yet been discovered.

By practising such a system of cultivating potatoes, the ground is stirred deeper and is better pulverized, and lies looser about the plant, and also kept cleaner and left in a superior state of cultivation for future crops than it could have been under the hoe system of culture, however well performed. And if the plan is properly executed, the hoe will not be required, except where the land, by previous mismanagement, has been well seeded down to weeds; and even in that case it will only be necessary to use it between the plants in the hills or drills.

I have seen and heard of a great many methods for raising (or *digging*, as the term is here) potatoes, but the best which I know of is to run a double mould-board plough through the centre of the drill or hills, after the tops have been thrown aside, and have one or two prongs, like harrow-teeth, attached behind the moulds, to harrow the furrow which the moulds throw out. By this operation, and by harrowing the ground afterwards, the potatoes can be taken tolerably clean out. Another plan is to run the cultivator between the drills or hills, and take part of the earth away on each side, and then take out the middle portion with a pronged hoe. The latter plan will probably take the potatoes out cleanest. But such implements can only be successfully used on land that has been kept clear of

weeds, or has had the long ones pulled before the commencement of the operation; for the plough or cultivator would be choked in such fields as are not unfrequently met with, in which weeds are so prominent objects that it would be difficult for a stranger to determine whether any thing else than weeds is to be found.

Respectfully, yours,

ALEX'R BICKETT.

Lowell, *December* 1, 1845.

From the Cultivator.

CULTURE OF POTATOES.

L. Tucker, esq.—In the last number of the Cultivator, you expressed a wish that I should give a particular account of the process of culture by which I have succeeded in raising the unusually large crops of potatoes which I mentioned to you in a former communication. There is nothing in my plan either difficult or original, and I am only surprised that greater crops are not generally raised; knowing as I do, from experience, that to produce 800 bushels per acre is, in this vicinity, an easy and simple process; provided the season is moderately favorable. For potatoes I prefer a soil composed of sand and clay in about equal proportions, resting upon a clay sub-soil. On such a piece of land, which has been in grass a few years, I haul out in February or March six four-horse wagon loads of good stable manure to the acre, (about 80 bushels to the load.) The manure is immediately spread and turned under by inverting the sod to the depth of ten inches at least. About the last of April spread on the inverted sod about three additional wagon loads of manure to the acre. Harrow the ground well lengthwise with the furrow. Cross plough to the depth of four or five inches, and harrow again. By this time the last manure applied is well mixed with the soil, and the land is in a fine state of tilth. The first of May, mark out the ground in rows three feet apart each way, with a large two-horse plough, to run as deep as the first ploughing. A good plan is also to let the bull-tongue plough follow in the furrows after the bar-share plough. This breaks up and loosens the sub-soil under the rows. A sub-soil plough would, I suppose, do the work better, but we have none, and the bull-tongue answers very well, as it loosens the sub-soil and does not throw it up. We plant the "*long reds*," using large potatoes for seed, cut into pieces with about four eyes each, and put four pieces in a hill; which takes about twenty bushels of seed to the acre. The seed is thus planted deep, on a loose mellow bed, and the ground, after the planting is completed, has a perfectly level appearance. The after culture is quite easy and simple. As soon as the plants are two inches above the ground, plough with the bull-tongue as near to the hills as possible; if most of the plants are covered up, so much the better. In two or three weeks plough again both ways; by this cross ploughing the earth is well loosened and thrown up around the hills, in a sort of hollow square, a little depressed in the centre, presenting a broad surface to receive the rains, and convey the moisture to the roots of the plants. The hoe is used to destroy such weeds as have escaped the plough, and to give the hills the proper form. Care is taken not to make those conical shaped hills which used to be the fashion, so admi-

rably calculated to carry off all moisture from the roots of the plants. I have found the *long red* to be the most productive of any kind of potatoes I have ever cultivated. I tried the Rohans two years, but found them to yield at least 30 per cent. less than the long reds. I have never tried planting in drills, and prefer hills on account of cross ploughing, which I consider very important. I know that 800 bushels per acre can be raised by my plan, for I have done it three years in succession, in 1842, '43, and '44. In the year 1844, the rot made its appearance in my potatoes, and I supposed that about 200 bushels were destroyed. Last spring, in addition to the other manure, I applied about 40 bushels of wood ashes and 4 bushels of refuse salt per acre to my potato ground. The ashes were spread with the last application of manure, and the salt sown broadcast after planting the seed. I think that the ashes and salt had some tendency to prevent the disease, as it was less destructive to my crop than it had been in 1844, while the crops of many of my neighbors suffered much more than in any previous year.

Respectfully, yours, &c. WM. McCOY.

FRANKLIN, *Pendleton Co., Va., January* 10, 1846.

From the Albany Cultivator.

THE POTATO ROT.

Mr. EDITOR: In almost every number of your Cultivator I find something in relation to the rot in the potato, both as regards the cause and the mode of prevention.

This, with us, is a disease of comparatively rare occurrence; and may, I think, be justly attributed to our peculiar method of cultivation; and, indeed, so far as I can understand, where this plan has been adopted no case of the disease has ever made its appearance.

In the selection of our land we prefer a light sandy soil, without *great* regard to *the richness* of quality; this having been well pulverized, is drilled to the depth of from five to six inches, and from one and a half to two feet apart. At the bottom of these furrows, and at the distance of eight inches, are laid the potatoes, which we prefer being cut with from two to three eyes to a piece; the drills are then filled nearly to the top with the best well littered stable manure; a small portion of dirt is thrown on this, so as to level the whole. The entire surface of the ground is then covered with leaves, (*we* prefer *pine* straw,) to the depth of from three to six inches.

It is to the adoption of this last method I particularly allude. The advantages of the straw are obvious; by its use is produced a more uniform moisture, as well as temperature of soil, which is kept perfectly free from grass and weeds, although no further attention is required either from the plough or hoe, until the maturity of the potatoes; which, for their size and number, I have never seen surpassed or equalled by any other method. This plan, with us, although not universal, is becoming much more general, and will, I think, in a short time supersede that of any other.

THOMAS C. HINES.

NANSEMOND, *Va., July* 12, 1845.

From the Southern Planter.

NEW MODE OF PLANTING IRISH POTATOES.

We would call the attention of our readers particularly to the following communication. Dr. Camm, the author, is represented to us as a gentleman of great observation and of the highest respectability. In the course of a hurried conversation, he informed us that the pieces of potato were to be put three or four inches apart in the hot-bed, and that the plants, or shoots, were to be separated by insinuating the finger and thumb as deep as necessary into the earth and plucking them off as close as possible to the old potato, exactly as has been heretofore recommended for the sweet potato. These plants are more hardy and certain of living than either sweet potato, cabbage, or tomato plants. There was another circumstance that the Doctor mentioned to us, which is not recorded in the communication; it was this—that the *rot* made its appearance amongst those potatoes that grew from the sets, whilst those raised from the plants were entirely free from any marks of this disease.

"*Mr. C. T. Botts:* Since the great improvement in the culture of the sweet potato, by forcing and setting the plants, I have been disappointed in finding no account in our agricultural journals, on the like treatment of the Irish potato. Having tested it for three years, I the last season cultivated them altogether in this way, and had six crops to succeed well, all of which were drawn from the same bed.

On the 30th of March, 1844, I had a piece of ground prepared in the usual way, and furrowed with a seed plough at six feet distances. Twelve and a half furrows were planted with a bushel of Mercer potatoes, two eyes to a set, and eight inches a part in the row. On the same day, I had half a bushel of the same kind cut across the middle, and the larger, or stem ends, put on one side, and the smaller, or seed ends, put on the other side of the same hot-bed. The pieces were placed so as not to touch, and covered with three inches of garden mould.

"April 27th, harrowed the land, gave the planted potatoes the first working, and had enough furrows made between the planted rows to set three and a half rows of plants drawn from the small ends of the potatoes, and one and a half from the large ends.

"May 22d, set one and a half rows from small ends, and two and a half rows from large ends.

"June 4th, set one and a half rows drawn about equally from each side of the bed.

"June 22d, set one row, and some few were set afterwards; so that nearly all the ground between the planted potatoes was filled up. The planted potatoes, owing partly to the drought, came up so badly that but for the experiment I should not have cultivated them; and I had peas planted where they were missing, to make the advantage in ground-room about equal with those from the bed, which were set at the same distance in the row, and gave me the finest stand I ever saw.

"On the 26th of July, the planted potatoes, as well as those first set, were in condition to be dug. Of the planted potatoes, twenty-four hills, taken together, and putting in all sizes, filled a peck, weighing fifteen pounds. Of the small ends sixteen hills, and of the large ends eighteen hills, filled the same measure, weighing sixteen pounds each. Of the peck of planted potatoes, the small refuse potatoes were considerable, and about

twice the quantity contained in those from the small or seed ends; whereas, among those set from the large ends were none of consequence. The largest raised from the small ends weighed eleven ounces, (larger than any from the planted,) and the largest from the stem ends weighed one pound and three-quarters, full weight—larger by eleven ounces than any I could hear of in my neighborhood.

"I have been thus particular in the above detail, that you may judge of the legitimacy of the following, among other inferences:

"1st. Half the quantity of seed will answer for the same ground—a saving of six to eight bushels (Bridgeman) per acre.

"2dly. Less than half the labor of cultivating will be sufficient, as the planted potatoes required two, while those set required but one working, and it is easier to work plants of some size than those that are smaller.

"3dly. Of those that *stood*, the quantity harvested were nearly twice as great from those set as from those that were planted.

"4thly. There was no perceivable difference in the time of maturing of plants drawn from different ends of the potatoes and set at the same time, although you will observe that the number of plants first thrown up were more than two to one in favor of the seed ends; and in the second crop, this ratio is nearly reversed in favor of the stem ends.

"5thly. A considerable difference in size of the set over the planted potatoes, and a more marked difference, in this respect, of the larger over the smaller ends of the potatoes, which confirms the general impression in this particular.

"6thly. This experiment shows an increase in size and quality, which we might very rationally expect, from having each plant separate, and those of the same age planted in the same ground and at the same time.

"Such as may be skeptical can readily test this method by setting the missing hills of their next crop from those that have more than one plant. As the Irish potato crop now engrosses considerable attention, I hope the foregoing may not be without interest to your readers.

"Your obedient servant,

"EDWARD CAMM.

From the American Agriculturist.

CULTURE OF POTATOES.

The December number of the Agriculturist contained a short article upon the potato rot, and an invitation to its readers to contribute facts relating to the *cultivation* of the potato.

My farm is upon the banks of the Connecticut, and the soil is of alluvial formation. Such soils are not favorable to the production of potatoes, as they are too close, and harden from the influence of the sun after rain. The porous, moist, upland, is congenial to the potato. Upon our *intervals*, [meadows or bottoms skirting the river] we prepare the potato ground precisely as we do for corn, by spreading upon the green sward coarse and unrotted manure from the barn-yard, and turn under as early as we can. After rolling and harrowing we plant upon the surface, in hills about three

feet apart in the rows, and make the hill as large as we can. We do not hoe more than once, except in wet seasons, when the weeds flourish.

I planted one piece in the usual manner as early as the middle of April, and on the last day of May I planted another piece upon the same swell of land, turning under a good coat of grass, to the depth of five inches. I then sharpened a stake, (not very sharp,) which was about three inches in diameter, and put an inch pin through it about ten inches from the bottom, so that by stepping upon the pin I could easily perforate the sod. I then began making my holes between the two first furrows, about 18 inches apart, and continued to do so in every fourth lap through the field. I then put one medium sized potato in each hole, forcing it down to the bottom of the sod, and covering it with my heel. After planting the whole field in this manner, I went over it with the roller, which left the surface perfectly smooth. After the tops were three or four inches high I plastered them, and covered the plaster an inch or two with my hoe. Before the tops got to be too large I went between the rows with a cultivator, and pulled the weeds out between the hills. The result of the experiment was very gratifying. The crop from this piece was almost twice as large as from the other. The potatoes were larger, and much finer for the table, and cost me not more than half the usual labor. I would observe that this experiment was made upon dry soil, and in a very dry season. The process of decomposition underneath the sod concentrated the moisture, and the unbroken surface prevented evaporation. When I harvested (which I think should be as late as possible, and avoid the freezing) I found that the tops came from below the sod, but the potatoes were upon the surface, some of them out of the ground. I shall try this mode again, and place the potatoes twelve inches apart in the rows.

I have escaped the rot, although all my neighbors have suffered from it the two past years. I cannot account for it; but, reasoning from analogy, I have formed the following opinion: that is, the disease is caused by an insect. The plant may be too mature, or not sufficiently so, when the insect appears, to suffer from such attack; therefore we succeed best when we plant *early* or *late.* This same theory would apply equally well to the supposition that the disease is the effect of the damp, hot weather of August.

In sowing wheat in the spring we know that we escape both the weevil and rust, either by late or early sowing; and I have noticed that the blast in the potato and the rust in the wheat come together.

WM. BELLOWS.

WALPOLE, N. H., *January* 13, 1846.

From the Boston Cultivator.

POTATO CULTURE.

I noticed a method of treating potatoes which struck me as very good, especially on old ground. First, furrow the field both ways, and then plant in the check or cross of the two furrows; cover them lightly, yet deep enough to have them vegetate quick. As soon as the sprouts begin to crack the ground, go into the field, and from the cart put a fork or shovelful of coarse or green manure on top of the hill; then plough between, turning the furrows together, and cover the manure. Always follow with a hoe, and see that the manure is well covered. As the rows

run both ways, when time to hoe, plough contrary from the first time, and very little labor is required to hill sufficiently and keep the weeds down. The manure is as safe in this manner as heaped up in the yard or field to wait the fall crop. It is not exposed to the sun, nor is it as likely to heat and throw off the ammonia and other properties essential to vegetation, as it would be in larger quantities or heaps. In digging the potatoes and ploughing again for the grain crop, the manure is completely mixed with the earth. I go heart and hand for putting all manure into the earth as soon as it can be got from the farm, whether coarse or fine, especially in the spring of the year, instead of heaping it up to rot and waste through the summer.

Mr. Demarest says he gets nearly double the quantity of potatoes from this method, to what he would without this manure. Coarse manure helps to keep the earth moist under it. I have seen potatoes vegetate and produce well, lying only covered with straw about six inches, and no earth over them. E.

Passaic County, N. J.

From the London Gardeners' Chronicle.

PULLING OFF POTATO FLOWERS.

We observe that a letter has been addressed to the editor of the *Hereford Times*, by Mr. W. Godsall, strongly recommending all persons interested in the potato crop to pull off the flowers diligently as they appear. We beg to second that wish. All experience shows that flowers of the potato are produced at the expense of that organizable matter which gives its value to the tuber, and which is diminished in quantity in proportion to the number of flowers that have been fed; for flowers must exist and feed on something, and that something is what would, if not removed by the flowers, descend beneath the ground and collect itself in tubers.

The mere production of flowers is a loss; but the mischief is infinitely increased if the flowers are succeeded, as they almost always are, by the berries. The actual amount of loss produced by each truss of flowers is not ascertained; but it is probable that if the flowers extract one ounce of organizable matter, the berries consume at least twice as much. Now, as potatoes are not grown for the sake of either the flowers or the berries, every particle of matter which is consumed by the plant in producing them is a dead loss to the grower.

The man who makes his potato ground feed flowers, prevents it feeding his children. Every ounce of matter consumed by the flowers is so much taken from the consumption of the family.

We cannot just now lay our hands on any precise evidence of how much is lost in this way. Mr. Godsall assumes it to amount to many hundred weight, or even a ton an acre; but he is in all probability under the mark.

A bunch of potato berries weighs, we will say, half a pound. Suppose that each potato plant bears half a dozen bunches; that makes three pounds of worthless produce. An acre of potato ground carries about 20,000 plants on an average; this gives 60,000 pounds of waste. But of this 54,324 pounds will be water, according to Mr. Edward Solly's experiments, and only 5,322 pounds organic matter. The latter, however, or two tons seven hundred weight fifty eight pounds, would, according to this calculation, be the amount of loss sustained per acre by allowing the potatoes to flower and fruit.

Admitting, however, that this is an excessive statement; supposing it to be wrong by even one-half—and it cannot hardly be so much as that—still there is the most ample evidence to show the immense importance of preventing the potato expending its energy in the wasteful production of parts which are of no sort of use for food.

[The above suggestions coming (as we presume they do) from the pen of Prof. Lindley, the celebrated botanist, are entitled to great consideration.]—*N. E. Farmer.*

From the Boston Cultivator.

ON REMOVING POTATO BLOSSOMS.

We have seen accounts of several experiments in removing potato blossoms, in which it appears that by this process the crops were considerably increased; and this seems reasonable in theory, as some kinds of potatoes produce a crop of balls equal to one-fifth the crop of potatoes, as we have learned by experiment; yet all experiments do not give uniform results. Some cultivators say that they find, from their experience, that the crop is no larger for removing the blossoms; others say that it is less.

A writer in the Ayrshire Agriculturist (Scotland) states that he made a small experiment; and according to the result, he had one ton less to the acre on that part where the blossoms were removed. His experiment was on the cup potato, which flowers, but produces no apples or seed. It is stated in the Hereford Journal, (England,) that a farmer in west Lothian pulled the blossoms from one row of his potatoes, 23 yards long, and that row produced 13½ lbs. more than any of the adjacent rows, on which the bloom was left.

We wish for our correspondents to make exact experiments this season, on this subject, and let us have the result. Better remove the buds before the blossom forms. Make the experiment by removing the buds from alternate rows, and weigh the produce.

As the qualities of the potato ball or apple differ considerably from the root or tuber, it may be that the juices destined to nourish the balls will not, on removing the blossoms, go to increase the roots. This view is not unreasonable. But it seems strange to us that the removal of the buds or blossoms will reduce the crop. And we think that there is some mistake as to this. We should think it more likely that in one case of the kind the experimenter made a mistake in weighing or measuring, than that nature played so singular a part; yet the ways of nature in some respects seem mysterious, and this is only because they are imperfectly understood. We are astonished at the lighting of a candle by the application of a piece of ice, or the production of ice in a red-hot crucible; but this is as much in accordance to nature's laws as ignition from a friction match, which, by the way, was at one time a wonder.

From the Gardeners' Chronicle and Agricultural Gazette, Sept. 13, 1845.

CULTURE OF POTATOES.

A great deal has been published respecting the culture of the potato; but as I have seen nothing which agrees either with my practice or theory,

I will detail my plan. My own family well know we can buy none equal to those which I grow, and that on a stiff surface soil, over brick clay, at the depth of 12 to 16 inches. In every other kind of propagation we are careful in the selection of the parents—so am I with my potatoes. Instead of planting, as too many do, just those which, in the spring, may happen to be left, my plan is this: When my potatoes are dug in autumn, in picking them off the ground, the best, of a middling size, (or perhaps I might say of a size just larger than the small,) are put aside for next year's planting. It is not necessary to cook potatoes to know the best. They are those which are truest to the proper shape of the sort, with a rough skin, but no canker or other blemish. Much as has been said to the contrary, I am very careful that they should be quite ripe.

The sorts I chiefly use are, ash-leaved for early, golden red or golden dun (both most excellent) for second, and the pine-apple kidney for late. The two former I always plant whole, at 2½ feet apart in the rows, and one foot between the sets. The last I give three feet between the rows. The ground of course cannot be too light and friable before planting; and I always think it better to have been well manured for the previous crop; but if I use any manure for the potatoes, I put it over the sets. These I put in very shallow, (just covered with the earth;) in fact, theoretically, I believe they would be just as well placed on the top of the ground. When they are six or eight inches high, I draw the earth to them from the middle space, which, being tolerably wide, gives them a bank sufficiently wide to grow and mature their tubers in. I never think of having carl, or mildew, or any other evil; nor have I any blight this year. I have to-day (August 29) been digging some ash-leaved, grown under the shade of large apple-trees, but quite sound and good.

CORYLUS.

From the Gardeners' Chronicle and Agricultural Gazette, Dec. 27, 1845.

ON THE PRODUCTIVENESS AND VITALITY OF POTATO SETS.

I send you two papers of mine, which have appeared in the "Irish Farmers' Journal." They are perhaps too much Irish to be of any use in England; yet you may find something in them to serve the holders of allotments. You will find that I allude, in them, to some curious facts, by which it appears that plants are productive rather from the space they obtain over ground than below it; and that, on rich ground, which we might suppose better able to sustain a close crop, if its nourishment proceeds from the root, grain sown at very wide distances gives an acreage return equal to that sown at much narrower intervals. Is it that the ammonia, light, and electricity of the air are not in sufficient quantity for plants at these intervals? The strength and length of the straw would indicate a greater action of light on the carbonic acid. Do plants, instead of absorbing by their roots their particular food, throw off by their leaves the peculiar matters they do not assimilate, and thus plants of different assimilating powers thrive together? And where they do not exist together, may not the soil absorb them, and in part retain?

J. M. GOODIFF, *Granard.*

[The following are the papers, B and C, alluded to by Mr. G.]

B.—ON THE PRODUCTIVENESS OF POTATO SETS.

There is, perhaps, nothing more worthy of inquiry than the differences which exist in the productiveness of plants under the same treatment, in the same soil, and in close contiguity with each other, and without any discernible cause for these differences; and, with a view rather to draw attention to the subject than to the conclusiveness of results, I beg leave to detail an experiment made with potatoes.

It occurred to me that the very great variations of productiveness of potato plants of the same kind of potato, and in the same drills and ridges, and in immediate proximity to each other, were not likely to arise from any peculiar property of the contiguous soil, or any gaseous influence in the air, but rather from either the manner of cutting the sets, their more or less exhausted state from previous growths, or from some internal construction indicated by the form of the potato, or the eye, from which the shoot proceeds. I submit this experiment with some hesitation, as from a mistake in over-manuring the ground it is not so decisive as it might otherwise have been. I had it manured on the surface after the potatoes came up, not recollecting that it had been previously dunged, and the consequence was that the plants grew with almost equal and very great luxuriance. The rows were seven yards long and two feet asunder, and planted on the 30th of May. This late planting allowed the first growing eyes of the potato to have made and lost some previous shoots. I say the first growing eyes, for it must have been observed by others as well as myself, that some eyes of the potato shoot earlier than others, and that some of the late shooting eyes (though generally nearer the stem of the potato) do not shoot at all when a whole potato is planted. I have, by cutting out the eyes of the potato as they successively grew, not only induced every eye to shoot, but have even got a shoot near the stalk, from where there was no perceptible eye till the shoot came forth.

From this property in the potato we may see how wasteful it is to plant it whole, as also the cutting it down in two parts, from the rose buds to the stalk, recommended by some. The first row was of the rose-eyes, (three-top-eyes) scooped out with a teaspoon in the form and about the size of the top of a man's thumb; the second row was of the bottom, or stalk-eye; the third, of the stronger eyes that had previously sprouted and lost their shoots; the fourth, of the later and weaker looking eyes that had not sprouted; the fifth, the scoops taken downwards, so as to take in the protuberance under the eye, and which, I think, may possibly contain sap-channels of the eye; the sixth, scooped upwards, so as to exclude the protuberance; the seventh, those projecting or nipple-eyes, which appear to be the result of a later growth, and are generally an aggregation of small eyes; the eighth, scooped downwards as the fifth row; the ninth, as the sixth; the tenth, as the seventh; the eleventh, deep-eyed potatoes; the twelfth, shallow-eyed, having a disposition to appear as the sixth; the thirteenth and fourteenth, deep-eyed, with a very deep-eyed red potato among them: the plants of this red potato all had the curl, and were unproductive. All the eyes were scooped—the direction of the scoop being towards the stalk in all, except those otherwise stated, as either upwards or more decidedly including the protuberance beneath the eye.

No.	Kind of set.	Produce, in pounds.
1	Top, or rose eyes - - - -	24
2	Bottom eyes - - - - -	14½
3	Strong eyes, that had sprouted - -	20½
4	Later eyes, that had not sprouted - -	16
5	Cut downwards, with protuberance - -	14
6	Cut upwards, without protuberance - -	14
7	Nipple eyes - - - - -	7½
8	As No. 5 - - - - -	20
9	As No. 6 - - - - -	14
10	As No. 7 - - - - -	5
11	Deep-eyed sets - - - -	11
12	Shallow-eyed sets, disposed to nipple - -	11½
13	Deep-eyed, mixed with a red potato - -	8
14	Deep-eyed, mixed with a red potato - -	16

In other experiments, I have found no difference in the produce of the top and bottom eyes. I did not expect to have found the early sprouting eyes, so late in the season, producing more than the eyes that had not previously sprouted; and this is contrary to an opinion that has lately gained ground, of the advantages attending early planting, previous to the potatoes sprouting. The experiment is in favor of cutting the sets downwards; but not very decidedly so, for in 5 and 6 there exists no difference, yet there is a decided one in 8 and 9. The deep eyes do not appear to have an advantage over the shallow ones, even where they appear disposed to nipple; while the decidedly nipple-formed eyes are very unproductive. But the most extraordinary difference is between 13 and 14, in which I am not aware there was any difference in treatment or seed; they both had equally intermixed sets of a red potato, that produced none but curled plants, with a few small potatoes under them. Had it not been so, they would, I think, have produced at least half as many more potatoes, and number 14 would at least have equalled number 1; and these are so much more productive from their being the outside rows in the experiment, I feel assured. They are a further confirmation of what I have frequently observed before, that the produce of a crop depends much on its having a free space above the surface of the earth and not below it. * * * *

Now, I stated some time ago, in the *Irish Farmers' Journal*, an unexpected result in an experiment made, with other views, of a great return in two rows of barley, at a wide interval of three feet six inches, and in a part of another row, where a wide space was afforded it, these two rows giving three pounds 9½ ounces, and three pounds 6½ ounces; while none other of the rows, at 21 inches apart, gave more than two pounds 5½ ounces, with the exception of the part of another drill mentioned above. These two rows, therefore, though at so wide a distance, would, in an acreage calculation, have produced as much as the closer rows of 21 inches. A crop of grain, then, might be grown in drills, at this distance, as weighty as in any other way, and a crop of turnips, parsnips, or other low-growing herbaceous plants, at the same time produced. This is found also to be the case with beans. In the case mentioned in the earlier part of this paper, of my potato experiment, potatoes appear to follow the same rule—of increasing productions at increasing distances.

In the probable scarcity of seed in the ensuing season, this may be an

object worth attending to; an equal crop of potatoes may probably be obtained with one-fourth the usual quantity of seed, and a very fair crop of parsnips also got—an excellent substitute for potatoes should a disease similar to that of this year, which very probably may, visit them in the next. In drills drawn at 16 inches asunder, one row of potatoes and two of parsnips should be sown successively; this would give a distance of four feet for the potatoes. In beds made three feet wide, with a furrow of $1\frac{1}{2}$ foot, in like manner a row of potatoes should be planted along the middle of the ridge, and a row of parsnips near each edge. These operations should take place as early as possible in the spring, not only as the parsnip is a slow grower, and therefore requires early planting, but that the potatoes may be got into the ground before they begin to decay in the spring, which, I fear, is not improbable; for, in the rot which commenced in the neighborhood of Killybegs, in the county of Donegal, about fourteen years ago, and which brought on famine and desolation to many, and for many years ravaged the country, the disease did not show itself till the spring, and it increased with the increasing warmth of the season; and this present disease, although differing in mode and in appearance, bears, as far as my recollection goes, the same perfume, and communicates the same taste to the potato affected with it. I cannot too strenuously press these remarks on the Irish public, nor can I urge too strongly the absurdity of a nation trusting to one sort of vegetable for its food, and that one that has for these fourteen years been a failing one. We have a warning afforded to us this year. If we neglect it, the most dreadful affliction may fall on us and our children.

What has been partial this year may be total next. It is a blasphemous neglect of the warnings of the Most High, bearing a false semblance of faith, to say, "God is good," and refuse to listen to his voice, spoken in the pestilence. I know of no crop that can equal the parsnip as a substitute for the potato, nor one that the Irish palate can so soon reconcile itself to. I call for exertion. Humble as I am, let me not call in vain.

C.—ON PROCURING EARLY POTATOES.

It has been recommended to plant potatoes before the end of January, and my experience tells me it may be safely done; but I think an earlier crop may be insured by promoting the vegetation of the potatoes in a warm house; and I am told that early vegetation is assisted by mixing them with turf-mould. I would scoop out the growing sets in succession as vegetation appeared. Thus, in time, the whole of the eyes would be planted, and a single failure could scarcely ensue. By planting sprouted sets I obtained in Donegal a crop of well-grown potatoes by the middle of June. Last spring, out of 18 large cup potatoes, weighing $7\frac{1}{2}$ pounds, I took 176 fine scoops, one inch in diameter and one inch deep; they weighed $4\frac{1}{2}$ pounds, and I had $3\frac{1}{4}$ pounds of refuse, capable of being used as food. A statute acre, planted in rows four feet asunder, the sets being nine inches apart, would take only 14,520 sets, weighing only three cwt. one stone, with a refuse of two cwt. and three stones—altogether $5\frac{1}{2}$ cwt.; but this refuse fit for food.

It has also been recommended to plant the sets nearly in contact, but not

touching, on a headland, to preserve them till the regular time of planting out.

When the rot first appeared in Donegal, I secured, in a similar way, a crop of potatoes on two acres of ground, where I should, in the common way of planting, have lost all. I made a hot-bed early in the spring—it could hardly be called a hot-bed, for it scarcely heated—covered it with about two inches of earth, and laid scooped sets (which are more convenient for transplanting than cut ones, as they drop more rapidly into the holes made by the dibble) within an inch of each other on it, covering them with about three inches of earth, and commenced transplanting them as soon as they generally appeared above ground. They appeared, though, when three or four inches high, to sustain no check, even when planted out in hot, dry weather, so that they were kept covered from the sun, when taken up, until they were planted. I planted them as deep as I could, even to the covering them when they were not much above the ground in the bed. Although the sets were in many cases completely rotten—so much so indeed as to fall off when removing from the bed—yet there was no failure among them; but of a quarter of an acre that I planted in the common way, not one set succeeded. The early growth in the bed is, I think, accelerated by laying a little loose straw on the top of it.

From the Mark Lane Express and Agricultural Journal, December 1, 1845.

POTATOES.

Table of the number of sets of potatoes, and total weight of the same, required for planting an acre, at the following distances, each set containing only a single eye and weighing one-half ounce, the distance between the sets in the rows being nine inches.

	Number of sets per acre.	Weight of sets per acre. Cwt.	lbs.
Rows 18 inches apart - - -	38,720	10	90
19 do - - -	36,682	10	26
20 do - - -	34,848	9	81
21 do - - -	33,188	9	29
22 do - - -	31,680	8	94
23 do - - -	30,302	8	50
24 do - - -	29,040	8	11
25 do - - -	27,874	7	87
26 do - - -	26,806	7	53
27 do - - -	25,813	7	22
28 do - - -	24,891	6	105
29 do - - -	24,033	6	79
30 do - - -	23,232	6	54

On poor soil, 18 inches between the rows may be considered a proper distance, as may be likewise the case with early, weak-stemmed varieties on any soil; and according to the vigor of the stems, richness, and depth of the soil, the distance may be increased to 30 inches, which is wide enough for the strongest growers, even on rich soil. It is to be remarked, that in some varieties the eyes are not abundant. With regard to such, the above number of sets will not be obtained from the corresponding weights, but in general it will be practicable, provided sound-eyed tubers can be employed. It is a *minimum* weight for an acre, but will probably have to be considered enough.

ROBERT THOMPSON.

RESULT OF A CHEMICAL EXAMINATION OF AN ASSORTMENT OF POTATOES AT HOHENHEIM.

BY PROFESSOR SIEMENS.

[From Riecke's Weekly Journal of Agriculture and Domestic Economy, 1843, No. 20: translated from Dingler's Polytechnic Journal, volume 88, page 374, by E. Goodrich Smith, of the Patent Office.]

In order to learn more closely the proportion of constituent parts of the potatoes here cultivated, they were subjected to the following chemical examination, and gave the following results:

The examination of these potatoes was made in the month of November of the previous year. At the same time was determined the *specific weight*, in this manner: A potato of middle size, after having been carefully cleaned, was accurately weighed, then fastened by a fine thread under the scales, and dipped into a wide vessel of water. Afterwards, before the air bubbles appearing in the water on the potato had passed off, the scales were again brought to an equilibrium, and the loss of weight which the potato had suffered by being dipped in the water ascertained. The first ascertained absolute weight of the potato, divided by this loss of weight, gave its specific gravity. Larger and smaller potatoes of the same kind exhibit, for the most part, somewhat less specific weight than those of the middle size, which usually weigh from 1,000 to 1,500 grains.* The contents in starch, fibre, albumen, extract, and slime, were determined in the following manner: 6,000 grains of clean potatoes were grated on a grater made of tin, with perforated holes. The holes of this grater were half a line distant from each other; and so there were 37–38 in a Wurtemburg square inch. The pulp obtained was washed in a hair sieve which had 1,600 openings in a square inch. Before the fibre became dry it was pounded in a mortar as long as any large portions remained visible, and then afterwards washed out again, so that the existing starch was wholly obtained. As soon as the

---

* A comparison of these results with the earlier published specific weight of an assortment of Hohenheim potatoes, shows some very remarkable differences. Investigations repeated in future years can only explain this: whether it be owing to difference of the season or a gradual deterioration of some kinds, or whether or not, generally, the specific weight in particular tubers of the same kind differs more than usual. The cause may often lie in the different degrees of ripeness; as, for example, the lesser specific weight this year of the blue filder potatoes entirely corresponds therewith, as this kind last year was not commonly ripe, and therefore was small and unpalatable; while usually they belong to the most mealy.

liquid showed itself over the starch it was poured gradually from the bottom on a dry filter of known weight, on which remained the portion which did not pass through, which was afterwards dried, and is marked as the *slime* or *residuum.* This residuum appears to consist in part of unripe starch, with some impurities.

The remaining *starch*, after repeated washings with pure water, is dried at a temperature of 25 to 30 Reaumer, as long as any loss of weight can be perceived. This is very different in different kinds, in reference to fineness and color, on which account attention should be paid in further experiments for this purpose on the same kinds of potatoes.

The liquid filtered from the residuum was immediately evaporated to one-third of its volume for the separation of the albumen, and the coagulated albumen separated by filtration. The quantity and condition of this showed itself likewise to be different in kinds of potatoes grown on the same soil, and with the same manure, but of which the quantity will be here given, as we have reserved the different conditions of the same for a further examination. In all the statements respecting the quantity of the essential constituents of potatoes, as well in respect to their use in distilling of brandy as in reference to table use and for fodder, the albumen of the potato is considered not in the degree it deserves to be, in regard to nutritiousness of albumen, in a selection of potatoes for table use or fodder.

The liquid filtered from the albumen was immediately evaporated without further regard to dryness, and brought into the reckoning as *extract.*

APPENDIX No. 5.

POTATO ROT IN THE UNITED STATES.

From the Albany Cultivator.

DISEASE OF THE POTATO.

Mr. Tucker: The subject of the disease which last year prevailed so universally among potatoes is one which has very naturally and properly called out the inquiries and conjectures of many investigators, and as yet no particular cause for its existence seems to have been concluded upon by the mass of cultivators. Some suppose that the membranes of the leaf are destroyed by an insect, and that the work of decay originates in this cause.

But of this theory—for it is theory, and nothing more—we are prepared to say that we saw (and so did every observing farmer, we must think) hosts of small black flies infesting potato fields in years long before we ever heard of the disease in potatoes, and the usual consequence was that the membrane of the leaf was eaten out, as somebody, in some particular instance, saw it last fall. Then, again, in proof of the innocence of the poor insect (who is certainly driven to rather hard fare, even for a mischievous fellow) in this matter, we must say that we saw with our own eyes, and no mistake about it, leaves of potatoes after they had become dry by the disease, as perfect in all their parts as any potato leaves we ever saw. Others are of opinion that the cause of the disease is owing to the "influence of a worm in the root;" but we have seen no statement of such animals being found in such locations until the disease had made some progress; so there must be some doubt in the case as to whether the worm does the mischief, or is attracted by the consequences of its having been done to feast on the corruption that ensues.

Last fall we ventured an opinion on the cause of the disease, which as yet we have found no cause to relinquish; but, on the contrary, from the facts we have collected and observations we have made, we have become more tenacious of its correctness. It was simply this—that, from some cause which we did not then and cannot now define to our own satisfaction, the potato vine was attacked with a rust similar to that we frequently see on the straw of rye and wheat; that, in the case of the potato, it first showed itself in a very small blotch on the side of the stalk, which continued to spread until it had gone round and through the stalk, when the latter, at the particular point of disease, became dry and hard, as though it had reached its maturity. The death of the top of the stalk of course soon follows, but the lower part remains green for a while. The conjecture (it was mere conjecture) we threw out was this: whether the sap which was now stopped by the dryness of the stalk in its usual channel of circulation, and of course prevented from passing into the leaf, its natural laboratory for preparation to return to the tuber and fulfil its accustomed service in giving it nourishment, did not necessarily return prematurely, and, either from excess of quantity or by bringing back some quality which had better been given to the winds, induce the disease in the tubers? Our own potatoes were too far gone to experiment much upon, when we, surprised with the novelty of the action, hit upon a single plan to adopt. It appeared to us, however, as soon as we saw *how* the mischief was progressing, that mowing

the tops was the best and perhaps only efficient method to pursue. A neighbor, whose crop was smitten long after our own, tried this experiment by mowing about half a field as soon as the tops exhibited symptoms of the disorder, and the result was satisfactory and cheering. Where the tops were so mown no appearance of the rot was ever discovered, and the potatoes gave all the evidence of maturity which the circumstances of the case could possibly admit of, while the other part of the field suffered as much from the rot as any in the vicinity. Here, then, is one instance in favor of our theory.

Other experiments were tried, of which we shall cite but one or two. In one case, a farmer dug a very few hills when the vines first showed symptoms of disease, and carefully buried them and let them remain until the usual time of digging, when they were taken out all sound, while the most of his crop had suffered essentially. There can be no doubt, we think, that when potatoes are dug so early as the rot came last year, they must be put in small bodies and kept cool, and excluded from the atmosphere. Their tendency to heat, and thus become heavy and insipid, warrants us in that conclusion; and so we infer that the letting them remain in hills with the tops taken off until the usual time of digging is a much cheaper and better way than to dig and put them in cellars, or on floors in piles.

Another course of proceeding which has come under our observation was adopted by some Irishmen, who had known this enemy to their favorite esculent "in the old country," and which it may not be useless to mention. When they saw the crop smitten, they dug it immediately, and piled the potatoes on the surface of the ground, taking care to guard them from sunshine until the job was completed, when they covered the pile entirely with clay. The result was probably as they had known it to be aforetime. Their crop was saved, and their potatoes of *good* quality. The clay undoubtedly acted as a two-fold agent—kept them cool, and excluded the atmosphere and storms.

We have only to say, in conclusion, that if any one can confute any point we have advanced, we shall be happy to have him do it. Truth and light are what we are looking after in this matter, and if we have advanced an error, the public good requires that it should be set right. And especially does the agricultural interest of our country require that this pestilence, which made such rapid strides in its advancement the last year, should meet with hot pursuit by every philanthropist, until its progress is stayed, if not effectually stopped.

Yours, truly,

W. BACON.

P. S.—There have been many experiments in planting potatoes tried in this region this spring, with reference to preventing the disease. If any thing of importance results from them, I shall give dne notice.

MOUNT OSCEOLA, *Mass.*, *June* 22, 1845.

From the Albany Cultivator.

POTATO ROT.

We give the following from a letter from Hon. John Crary, of Salem, in this State. His suggestions are worthy the consideration of our farmers:

" *The cause of rot in the potato, and the way to prevent it.*—The rot in the potato occurs in hot, dry seasons, and the heat and drought prevent the ripening of the potato, and disease and decomposition follow. I observed during the last summer a difference in the potato crop on the same land. Those potatoes that were covered deep were good as usual; those the covering of which was shallow, were useless, particularly for the table. The first symptom of failure is in the stalks of the potato; they become dry, and the leaves turn black; the growth then ceases, and the potato becomes rotten before it is ripe. The fibres that connect the stalk with the potato quit their hold; and when you grasp the stalk and pull with a view to raise the potatoes out of the hill, the roots break and leave the potatoes, or rather slip out of the hill without raising them."

Mr. Leroy Patillo, Monroe, Georgia, writes us that he thinks the rot is caused by small insects, and advises rolling the seed-potatoes in sulphur before planting them. He informs us that he has used sulphur with good effects around plum trees in which insects had perforated the bark, and from which the gum oozed out.

From a letter received from Elisha Hammond, of Conesville, N. Y., we extract the following facts in relation to the rot in potatoes:

1. "On dry, cool land, not very rich by putrescent manures, the crops almost entirely escaped."
2. Defective potatoes fed to hogs, in connexion with sulphur and charcoal, have produced no injury.
3. In a field of potatoes, some of the rows crossed places on which stumps had been burned, and other rows a spot where potatoes had been buried the year before, and the straw used about them turned under for manure. The crop was much more rotted on these places, especially over old potato-holes, than elsewhere.
4. Lime has been said to be a preventive of rot. It proved *not* so in this case. Some coarse lime had been spread on a part of the field. Some hills where the lime happened to be scattered were particularly examined, and found much more rotted than where nothing was put.
5. Plaster was used on most of the crop. Two rows were left through the field without plaster—no difference could be discovered between these and other rows, in the condition of the potatoes.

From the Worcester Spy.

POTATO BLIGHT.

I grieves us to state that the blight which caused such destruction to the potato crop last year has thus early commenced its ravages the present season. We have examined a field belonging to Governor Lincoln, which, we are assured, exhibited a perfectly healthy appearance on the 3d inst. On the 5th, portions of the vines showed indications of disease, and on the 7th about one-half of them were more or less shrivelled, many of them shrunk to one-half of their former dimension, and some of the leaves already turned brown and nearly dry. The potatoes were of the red variety, sometimes called the peach-blows. The seed was selected, and in a fine and apparently healthy state. We opened one of the hills most affected

with the disease, and found the seed still sound and apparently healthy. Some of the new set potatoes were about the size of a robin's egg, and looked well. So far as we observed, the disease appears to commence at the upper part of the vine.

We invite the particular attention of farmers to this subject. We hope that such careful and accurate observations of the commencement and progress of the disease, the present season, may be made and recorded, by men of judgment, as will lead to some more conclusive indications than have been heretofore obtained of its origin and causes, and that they may result in the discovery of some efficient and adequate remedy for the appalling evil—an evil that threatens the destruction of a crop which affords one of our most abundant and most wholesome articles of food.

Mr. Pearce, of Hamburg, who is an excellent and observing farmer, saw that his potato vines were affected, and pulled several hills to examine the roots. They were sound, and left separated from the stems or tops. By this separation these hills wholly escaped the rot, while the potatoes in all the adjoining hills were rotten at the time of harvest.

From the Albany Cultivator.

There are two facts which I observed in my field, which I have not seen noticed in your paper. The first is, that the disease was confined to the tubers nearest to the surface; those lying deep were unaffected. The second is, that the rotten potatoes were full of long white worms. I saw nothing which looked like fungi, with the naked eye; but it did not occur to me to examine them with a microscope. The odor was intolerably fetid.

N. N. D.

For the Indiana Farmer and Gardener.

POTATO BLIGHT.

Mr. Editor: I have just returned from an examination of my friend Robert Morrison's potato patches. A disease not heretofore noticed in this section of the country has attacked many of his vines; and, that the readers of this paper may be made acquainted with its character, I proceed to give the results of our researches. In all cases of inquiry into causes, I conceive it to be important to right deductions that we should first lay a broad foundation of accurate observations. When these observations are sufficiently numerous and rightly arranged, a correct theory springs almost spontaneously out of them.

My present purpose is merely to aid in accumulating data, and to distinguish this from any other affection to which our potatoes may be liable.

1. There are three different lots of potatoes which we examined. One patch was planted so early as to have been prostrated by two successive frosts. The other two patches were planted about nine weeks ago.

2. One patch of the late planting is in a well-manured sod ground; the others in a poorer soil.

3. All these lots are affected with the disease; but the frosted potatoes the least.

4. The disease, in every instance, was found to be confined to the *vines*. These were affected generally near their entrance into the earth—a few inches below it, and a few inches above it.

5. A person, in a general review of the field, would perceive nothing but a luxuriant crop of potatoes; on passing watchfully along the rows, he would discover here and there some prostrated vines with *wilted* leaves. On close inspection he would find, at the points named, a perfectly *dry* decay of the stem: the pith is entirely gone; the cuticle is also removed or dried to imperceptible thinness; and nothing remains but the ligneous fibres, whitened by disease, and sometimes separated laterally. This is the worst stage of the disease yet observed. The parts below this point are perfectly sound at present.

On turning to other stems indiscriminately, whose leaves and vines are apparently in the full vigor of health, we perceive the earliest encroachments of visible disease. Here we see a little discolored patch of cuticle dried up and sunken to the ligneous fibres below; the parenchymatous matter among the cuticular tissue having disappeared. Let us gently scrape away this dead cuticle, and we shall find the ligneous texture yet living; but in the next plant this is also decayed; and in still another we witness the destruction of half the pith; and in another the pith is all gone; and then we arrive at the last stage, or total rottenness. In most instances there are several such patches of cuticular decay, of irregular figures; but there is a well-defined line of separation between the dead and living parts. Let us slice, longitudinally, one of the vines in which these spots of decay have penetrated into or through the pith, and we shall find portions of solid and apparently sound pith in the intervening portions of the stem.

6. In several instances the returning sap being interrupted in its descent by the cuticular decay, formed small tubers (perfect potatoes) just above the diseased point.

7. In a very few cases the blight had affected the branches of the vines; and in as few cases the decayed pith was found in a slushy state.

There is no apparent erosion of the cuticle; but the idea is suggested of all the pulpy matter in it being abstracted, and the cuticular film collapsing upon the parts beneath.

We may safely say, upon these observations, that the disease undoubtedly commences on the *exterior* of the vines; and that the upward circulation is continued long after the downward current is partially, if not wholly, intercepted; that the disease tends to penetrate *into* and not to pass along the vines; the tops perishing only when no nourishment can be obtained from below.

If the tubers should become affected, I will endeavor to report the facts, unless anticipated by others.

J. T. P.

From the Boston Cultivator.

THE POTATO BLIGHT.

The Bennington Gazette says that Milton Burrill, of Stockbridge, has been investigating very fully the subject of the disease, and is now fully con-

vinced that he has discovered the true cause in the shape of an insect. He showed us a sample of the insect, which, through a strong magnifying glass, looks formidable, though so small. He is convinced that every potato field in that vicinity is destined to fall as last year. He has visited many gardens and fields around us, and finds them all giving evidence of disease. If the cause is discovered, we hope the scientific in our laboratories will soon make known some practical way of getting rid of the enemy—though we fear the remedy, if discovered, will be too late to save the present crop.

We have understood that house ashes, spread on the hills around the vines, after they have grown a few inches from the ground, is not only a remedy for the blight, but greatly facilitates the growth of the potato on some soils. It is very easy to make the trial.

The editor of the Genesee Farmer, Dr. Lee, has made extensive examination of the potato crop throughout central New York, and finds in all cases that the curling and blight of the vines is attended by an insect. The parent is probably the beetle. It punctures the vine just above the ground, and deposites its egg in the pith of the stalk, where it hatches. The larva eats off all the stalk but the outer bark, when the vine withers and dies.

Dr. Lee thinks that this prevents the ripening of the tubers and disposes them to decay. The blight, it is found, will be even more destructive than last year.

From the Northampton Courier.

DISEASE IN POTATOES.

We were this morning shown, by Dr. D. Stebbins, a potato leaf taken from vines in his garden, upon which insects or worms had commenced their ravages, which proved so disastrous last year. The leaf was nearly consumed, and the insects were yet busily at work. Dr. Stebbins is sprinkling his potato vines with tobacco liquid, and finds it to be an effectual remedy. Will others try this method of exterminating these destructives?

From the Massachusetts Ploughman.

POTATO BLIGHT IN MAINE.

Mr. Editor: Hastily I drop a few lines in relation to the "potato blight" (so called) in our place and vicinity. I am sorry to say, in the opinion of many here, from present appearances, our crop will be shortened more than one-half. There is, however, some uncertainty how this may turn out. Certainly, appearances are bad enough.

I have examined one or two pieces affected, and find the *blight*, if so it may be called, caused by an insect of the species *aphis* or *plant-louse;* and so rapid is the ravage in some fields, that the tops bear somewhat the appearance of having been touched by the frost. Probably, wherever the insect attacks, the tops will prematurely die. We would caution farmers not to be in too much haste to harvest their potatoes, though the tops may be dead. The bottoms, by remaining the usual time in the ground, will be

likely to improve. Besides, I am inclined to the opinion, by letting the potato remain in the ground till the proper time to dig may tend to make it keep better after it is dug.

We hear the same complaint made in many other places. We hope farmers will be observing on the subject, and note as many facts as possible. For one, I intend to watch carefully the progress of this *blight*, (or perhaps more properly termed insect ravage,) and note the result. Perhaps I may find occasion hereafter to add more on the subject. For the present I conclude by saying this insect, most likely, is the cause of the rot in the root. We shall soon see.

Respectfully,

B. F. WILBUR.

Butters-vale, *August* 26, 1845.

We approve of the practice of letting potatoes remain in the ground till they are fully ripe. As to the cause of the rot, we are uncertain.—Editor.

From the Massachusetts Ploughman, Sept. 20.

PLANT-LICE ON POTATO VINES.

Mr. Editor: Since my letter, hastily written the other day, I have observed and thought more upon the subject—the substance of which I beg leave to lay before your readers.

Naturalists have described numerous parasitical insects; but among them all I do not find a single description in the books which exactly answers to the *aphis* of the potato—for so I shall term it. It is, however, so like the aphis of other plants, it cannot be mistaken as to its class. I never have seen any thing of the kind on potatoes before; others perhaps have.

Perhaps it may be a matter of interest to some to have a brief outline of the insect. It is of a transparent green color, varying in size from that of a tobacco seed to that of a duck-shot; the largest sized have wings. They are generally found on the under side of the leaf; wherever they feed, the blight shows itself; the probability is, they extract the vegetable juice or sap, the loss of which to the plant causes the mischief. If only the stem of the leaf be attacked, the whole leaf withers and dies.

I remember, when the blight struck my potato crop in 1838, the tops looked at that time very much as now. The bottoms also were then affected. But I did not think, at that time, to look and see whether any insect preyed upon them, as now. I think, however, most likely they did. Last year I did not notice much that appeared like blight in my potato field, though the bottoms, in spots, were some affected with the rot at harvest time.

I know no remedy to apply as a preventive, or that will stay the work of mischief after it is once commenced.

Whether any peculiarity of the present season can be said to give rise to this pest or blight, is perhaps difficult to determine; (the season here, from the middle of July up to the present time, has been uncommonly warm and wet;) or whether *this blight* will be followed with disease in the root, similar to that of last year, is a matter as yet alike undeterminable. Time, however, will soon tell. It is to be feared the rot will follow.

It is to be hoped farmers will (for they of all others have the best opportunity to) be observing upon the subject, and note as many facts as possible for the general good of all who cultivate this useful root.

Potatoes, in this vicinity, up to within about ten days or a fortnight, have looked very promising of a heavy crop. The reader is aware, I suppose, vegetation *here* is much later than in Massachusetts. *There*, probably, the potato crop is now nearly or quite ripe; so that, if the disease prevails there, it must have commenced proportionally earlier to cut off the crop.* How is this?

Perhaps there is no crop grown in New England, excepting hay, the loss of which would be more severely felt than that of the potato. It is justly a valued root; it constitutes a cheap and wholesome food for man and beast; and it is sincerely to be hoped we are not to be deprived of it.

After all, let us not be too much alarmed; it may not prove so bad as now appears supposable; or, if we should be in a great measure deprived of this valuable vegetable, let us reflect, the Hand that gives has an equal right to withhold. Let the Most High reign, and man be wise and adore!

If any thing further in the progress of the disease, worthy of remark, should occur, I shall endeavor to communicate. Hope others, where the disease prevails, will do the same.

Respectfully,

B. F. WILBUR.

BUTTERS-VALE, *August* 30, 1845.

From the Massachusetts Ploughman.

POTATO CROP IN MAINE.

MR. EDITOR: I have just returned from Dover, the shire town of Piscataquis county; in passing to and from which my way lay through several of the best farming towns in the county—Sangersville, Foxcroft, and Guilford. The farmers in these towns tell me their potato crop this season is nearly or quite a failure—some will hardly get the return of their seed at harvest. I was at the trouble of examining several fields, and in every instance found the *aphis* preying more or less on the tops. The rot, as apprehension was expressed in a former communication, has set in. No one can tell how far the disease will extend. Fears are entertained that the crop will be entirely lost, whether harvested early or late. I think, of the two, late harvesting the safest. My reasons could be given if necessary. Some have essayed to save their crop by immediate harvesting and selling to shippers; but shippers are afraid to buy, fearing the mass would rot before it could be transported to a foreign market and disposed of.

I shall not attempt to theorize on the subject of this potato disease, (for so, I suppose, every body is agreed to call it,) though I am strongly of the opinion the *lice* on the tops are the sole cause of it. It is very natural to suppose a premature decay of the tops will have a corresponding effect upon the bottoms.

* Since writing the above, I learn, by the Ploughman of August 23, that the drought is so severe in Massachusetts the potato crop will be likely to be very light, and that the people there will be obliged to depend on Maine for a supply. It will be a sad thing indeed if we should not raise any to spare; and sadder still if we should not raise any to supply, which is feared by some.

Near the city of Bangor, I understand, some of the farmers are already engaged in ploughing in their potato crop, not being considered worth the harvesting.

The failure of the potato crop is regarded here in Maine (as well it may be) as one of the greatest calamities to the farmer's interest. It is to be hoped this trouble will prove to be of temporary standing—that another year it will not reappear.

Respectfully, yours, B. F. WILBUR.

From the Massachusetts Ploughman.

We presume the following communication is from the pen of the Hon. Morrill Allen. It is copied from the Old Colony Memorial:

POTATOES.

The disease in potatoes, which in some sections of the country nearly destroyed the crop of last year, has not yet progressed to any very alarming extent in the county of Plymouth. But there have been sufficient indications of its existence and advances to justify some general attention to the subject, and the employment of such preventive, or remedial means, as may seem to cultivators the most likely to prove efficacious. Until the the causes of malady shall be more satisfactorily investigated, no rules can, with implicit confidence, be given for the treatment. The farmers must do as physicians are sometimes obliged to do, in cases of undefined bodily disease—prescribe to the symptoms. This practice is attended with great uncertainty, yet the results of it in experience sometimes prove highly valuable. The different causes to which the disease in potatoes has been ascribed, lead writers to suggest a great variety of remedies in accordance with their views of the probable origin. Let farmers select and apply such as their reason and judgment best approve, and it may be that merely practical men will, in the course of their experience, clearly prove what theory has hitherto failed of doing—the moving cause of the difficulty. If, as supposed by some, it be of insect origin, then salt and lime would seem proper applications; and these are also strongly recommended by persons who think that fungus is the producing cause of the disease. Those who suppose it arises from atmospheric influence may properly apply the same means which would be recommended by those who believe it the result of excessive growth. Preparation of the soil, and a course in the cultivation likely to produce an even growth, is unquestionably important in this and other crops. Some persons seem confident that the rot in potatoes results wholly from deterioration in the seed. If this be true, we may not expect to avoid the evil merely by sending to another place for seed potatoes; we should renew them from the balls. This is a process requiring some patience, but we know of no easier method of entire renovation. We suppose renewal can be approached in successive plantings of unmatured potatoes. These have often been strongly recommended for seed, not only for the purpose of avoiding disease, but as a means of increasing the crop. It is manifestly contrary to what we regard as a general law in vegetation, that the most perfect seed produces the healthiest and most fruitful plants. There are, however, several reasons for believing that the potato may be an exception to the general law. The vegetative principle is not so concentra-

ted in the potato as in most other articles. It can be produced from the balls, the bulbs, or from sprouts which have grown in the cellar, or the earth. The vegetative principle being so widely diffused, it may be reasonable to suppose that the perfect ripening of the potato to some extent weakens its power of reproduction. That power, after the complete maturity of the bulbs, may be more perfectly concentrated in the balls. The experiment is easily made, and it is hoped that many farmers will this year plant potatoes for the next year's seeding as late as the 25th of June.

M. A.

Pembroke, *May*, 1845.

From the Farmers' Monthly Visiter.

We have not yet, in all the speculations of the curious and the scientific on the subject of the recent disease in potatoes, seen any thing to throw light enough to enable us to take a single step towards a remedy. In raising thirteen hundred bushels of potatoes last year, we had congratulated ourselves on an entire escape from the disease complained of by the most if not all our neighbors. We had disposed, to good advantage, of something like half of our crop; and we thought we should do better to save the remainder until the opening of spring, by then sending them to the Boston market. As the most safe kind, we had planted half the ground with long reds the two last years. In the fall of 1843 our long red potatoes were laid in the ground, in a bed not over two feet deep, covered with a coating of green hemlock boughs, and these covered with the surrounding soil, so that the winter frost could not reach through. The potatoes in the following spring came out as fresh and fair as they were on the day they were covered. Precisely the same way and near the same spot did we, in October last, dispose of about five hundred bushels of the long reds, the kind that were supposed to be proof against the rot, and near them, in a continued bed, about one hundred bushels of the round pink-eyed potatoes, an earlier kind. The pink-eyes came out as good as they were where they were covered; the long-reds were a mass of rottenness, so general that, of the whole quantity, not a bushel was taken out to be saved. We believe the potatoes suffered from the disease, because, a few days before they were dug, their growth was arrested by the sudden dying of the tops, which seemed to be stricken as with the blight, which frequently takes place at the earlier season. The vines being thus killed, we dug them perhaps a fortnight earlier than we might otherwise have done; and it was observed, when they were disposed of in their bed, that the skin peeled off easily. The top of the bed was kept open, as far as it could be done safely, until the approach of severe frost. We are inclined to think that the potatoes perished in consequence of being taken out of the air perhaps a fortnight too soon. Only a part of the same potatoes, dug at the same time, and laid in the bin of a cellar, above ground, adjoining to a basement kitchen, where a fire is kept continually, suffered from the rot; the potatoes remaining of these are some of the best we have ever seen at this season of the year. The potatoes of last year, disposed of in the same position, were greatly improved from the exposure to the air and heat from the kitchen; the long-reds of the present spring seem to have been benefited from the

same exposure; so that in the two positions of the years 1843 and 1844 the case was exactly reversed. We saved the potatoes where they were before lost, and we lost the potatoes where they were before preserved. Our belief is that the effects of the disease, which appeared on the killing of the vines, might have been avoided by keeping the potatoes in the ground until they were perfectly ripened.

Most strange and unaccountable is this potato disease. Sometimes we have seen one kind of potatoes (the Chenangoes for instance) half rotten at the time of digging, and some of them indicating the rot by specks on the end; while alongside, in the same field, other kinds of potatoes were entirely free from rot, or from all indications of disease. Other fields of the same kind of potatoes escaped the rot entirely. The richest soil seems to have been most liable to the rot. The high grounds of this State, the latest broken up pasture grounds, have commonly produced the best potatoes. Of last year's production it is believed that in these grounds the greater portion of the crop was lost; more than in the grounds where the blight had in former years been more common.

From the Massachusetts Ploughman.

DISEASE IN POTATOES.

Mr. Editor: Many, various, and often contradictory reasons have been given for the disease in potatoes the last season. Some have said it was caused by *wet* weather; others, in a different section, by *dry;* others by warm. Some have laid it to manure in the hill; others say, when there was none in the hill they were equally diseased. Some think lime, ashes, or plaster, has prevented the disease; others' potatoes, where these articles were used, have been as badly diseased as any. Some have laid it to the potatoes having been so long planted without reproducing from the seed. I have several kinds produced from the seed within a few years, and they were as badly diseased as any. Some lay it to a particular dew; others to a particular atmosphere.

Now, it is evident that these are not the causes of the disease. In York State it commenced two years ago; last year it was much worse, and reached this State, and will probably be much worse here this year than last.

This morning I examined my potatoes, and found some of the top leaves and stems dead, and many of them wilted; and among them a little bug, about the size of the cucumber bug, with a sharp beak, with which he was piercing the stems. On further examination, I found them on almost every hill; they were very active, and, by dodging or flying, would elude my grasp; wherever they punctured the stem, it would seem to wither almost as soon as if broken.

Now, my opinion is, that these bugs, by puncturing the stem, drawing off the sap, and perhaps poisoning it, are the cause of the disease; and the tops being thus affected before the potatoes are ripe, causes the root to rot.

On referring to Harris's Report on the Insects of Massachusetts, I find this kind of bug is the *Phytocoris lineolaris*, of the order called Hemiptera, and is described on the 161st page.

LEWIS FORD.

Cummington, *July* 14, 1845.

From the American Farmer.

POTATO BLIGHT.

To the editor of the Tribune :

Knowing that you feel a deep interest in the welfare of the farmer, I send you a few observations on the disease of potatoes, so prevalent last year, which I think I have discovered, and perhaps a remedy.

This morning, for the first time, I observed a few tops of the potatoes in my garden beginning to wither and curl up. Supposing that the cause might be near at hand, I commenced a critical examination of several withered tops, to discover it if possible. I soon found a green fly, about one-fourth of an inch in length, upon every top that had begun to wither, and on most of them two; some had four, a few six. On one top I found four young flies, about one-half the size of the adult, and on three others one each, about one-fourth grown.

The insect, I thought, must be the cause of the disease commonly called the curl-top or potato rot, since I found it on every diseased top in 30 or 40 cases, and usually on that part of the plant which had begun to wither near the healthy part of the stem. On the stem of one where the fly was, there was a small globule of viscid transparent liquid. This stem had begun to droop, but only so that it would scarcely be observed. Another globule on the upper side of the curled leaf, on which a fly was sitting, was found to be sweet. Many of the leaves that were much wilted felt as if a glutinous liquid had been spread upon the upper surface. These questions, then, naturally arose :

Does this liquid exude from the plant and attract the fly which is innocently sipping his nectar? or, does he perforate the stem and cause the exudation, that, like a malicious parasite, he may extract the life from this useful root? It appears to me that the insect must be the cause of the exudation, for this reason—that it was found on no plant that did not have a fly upon it.

In almost every case two flies were found upon the same plant, differing a little in size and color; the less being of a darker green, and the larger containing many eggs, which it appeared to be depositing. Only one egg was found in the stem of the plant; yet there were many places apparently stung upon the diseased stem, and the effect of this reached down in some cases three or four inches in the heart of the stem; otherwise were hollowed down as far as the healthy part.

From the above observations these conclusions appear to be evident—that the sting of this fly causes the curl-top; that it breeds upon the stem, and the numerous progeny live upon the plant, sucking up its juices and destroying its vitality. As a *remedy*, I amputated the diseased part, and destroyed all the flies I could. About 10 o'clock I sprinkled soap suds upon one small patch, and none were found upon it at night, though many were found upon another piece that was not showered. An hour before sunset I sprinkled the suds left from washing upon the whole.

The flies can perhaps be driven out of the field with a brush, where it is not convenient to shower them. Yours, &c. E. B.

POMPEY, *N. Y.*, *July* 14, 1845.

P. S.—Tuesday morning another examination was made, and only one fly was to be found on the piece.

Editorial remark.—We readily conclude that the green fly found on the potato vines as above described would affect the quality of the potatoes,

preventing their maturing; and, if left for any considerable time in the ground after the tops had begun to decay, would produce a second growth, by which the tubers would be rendered useless for cooking; but we doubt whether the fly here spoken of is the cause of the *general* rot which has been so prevalent of late years. We incline to the belief that rot is to be attributed generally to atmospheric influence—an undue or premature spring-like weather in early fall, causing the potatoes which are at a vigorous growth, though not fully matured or perfected, to begin to shoot or to grow in manner as though they had been planted for the purpose. This premature process ferments the tubers to an incipient state of decomposition, and hence the withering of the vines and the consequent deterioration of the crop. We are strengthened in the opinion by the same idea thrown out by Mr. *Gowen*, of Mount Airy—good authority, as all will allow—in his Report of Crops in 1843, as published 29th May, 1844, in the American Farmer, to which we would refer our readers.

For the Boston Cultivator.

THE POTATO MALADY.

Messrs. Editors: Your extracts from Arthur (see Cultivator for June 28) are interesting and deserving regard. There is reason in the belief, that the potato would be found to bleed less on cutting in the autumn than when cut at the time of planting; but to suppose that by such an arrangement the plague is to be stayed, is "all a hum," hundreds of acres, the past years, having been planted with whole potatoes, which ought, therefore, to have been thus preserved from disease; but these crops, as well as those produced from every "variety of seed, culture, soil, times of planting, different modes of manuring," &c., &c., have suffered alike and in the same degree. What need, then, of further witness?

Since writing the above, I have examined a field of ten acres of potatoes, about one-half of which were planted with uncut potatoes of small size; the remaining portion of the field being planted with cut seed, the operation of cutting having been performed at the time of planting, one eye in a piece; and it is but common honesty to confess, judging from present appearance, (the crop is now in bloom,) the uncut seed "have it." But this is a remarkably genial season, and there will, therefore, be no general complaint of "plague"—so the premiums offered by the "American Association" for the best essay, &c., might as well stand over for the present.

Our late crops of potatoes, those planted after peas, look finely; the late rains and very warm and growing weather having rendered them plague-proof. But let me relate a very curious fact, for the consideration of the learned. The day of planting my crop was excessively hot; but, except one row and a half across the field, the sets came up very regularly, which put me to a nonplus to account for such a singular and very perceptible failure; after a minute's reflection and investigation, I found that this row and a half had been left uncovered; the sets all the while exposed to a burning sun on a sandy soil, during the time the men were at dinner—say about two hours; and on calling on a neighbor who had complained of having just such a galled spot on his potato field, I found the very same effect following precisely the same cause—the exposure of the cut sets to the hot

sun at noon: so that, drawing the burning sand over these sets after two hours' exposure may be considered as somewhat like making a potato pie of them, and they were no doubt well cooked by the process; sufficiently so, at least, to prevent them from vegetating. C.

Gloucester Co., N. J.

From the Portland Bulletin.

DISEASE IN POTATOES.

At the farmers' national convention, held in New York city, the disease among potatoes was the subject of considerable discussion and remark. Mr. Robinson submitted an address to the people of the United States, urging the importance of investigations into the cause of this singular disease, which has hitherto baffled the efforts of science and experience to withstand its progress.

The farmers in Maine are particularly interested in this matter; during the past season, three-quarters of the potato crop of our State has been destroyed by this singular epidemic. The consistency and quality of the soil where the disease proves most destructive should be carefully noted; experiments should be tried of planting in new places and in different kinds of soil, with manure of every description now in use, and without any kind of manure whatever, and cognizance of any and every other circumstance calculated to throw the least light on the matter should be taken.

Gen. Tallmadge seemed to think the origin of the disease might be "in the natural course of vegetable decay and extinction of genera, so often observable in botanical history. He alluded to the extinction of the mammoth species of animals long ages ago—to the disappearance of the weed known as St. John's-wort, which but a few years since was the greatest enemy of the farmer, and is now so scarce as to be almost unattainable even for purposes of curiosity. He suggested that our farmers raise potatoes from the *seed* instead of the *root*, and also seek new kinds of potatoes in Mexico and Central America."

We think the suggestion of Gen. Tallmadge, of growing potatoes from the seed, an excellent one; hope our farmers will improve upon it, and will take all the other precautions calculated in any way to elucidate the subject.

Remarks by the editor of the Boston Cultivator.

Too much dependence is placed on obtaining new varieties of potatoes from the seed, with a view to prevent the rot. If the seed be selected from hardy varieties, that are known to resist the disease better than other kinds, some advantage may be gained. But the idea that the seed from a very tender variety will produce a hardy kind, is as absurd as it is to suppose that the offspring of a feeble, degenerate race of animals will be strong and healthy. The general law of nature is, that like produces like. Therefore it is important to select seed from a hardy race; and it would be well to plant several hardy sorts together, and then select from them, as in this way an improvement might be made by crossing.

For the Farmers' Cabinet.

DISEASE OF THE POTATO.

Mr. Editor: I have recently read a number of articles upon the "disease of the potato," and have been struck with what seems to me a deficiency in the reasoning on the subject. I formed an opinion in relation to the matter more than a year ago, in consequence of some investigations I then made, and subsequent readings and examinations have confirmed that opinion. I will give it to you for what it is worth. If it is not correct, perhaps it will lead to the truth—in which case I shall be abundantly repaid for my trouble.

It is well known that the substance forming the cells of all plants is a compound of nitrogenous matter with one or more of the alkalies, together with silex, &c. It is also well known, that if the cellular matter is deficient in alkaline substances, &c., it is comparatively weak, and unable to contain the matters deposited in it. It is well known, too, that the alkalies regulate the formation of the acids in the healthy vegetable, and that when there is not a sufficient supply of alkaline bases, the vegetable either contains a superabundance of acid or its growth is impeded. In the former case the vegetable is not fit for culinary purposes.

Now, I believe that in the case of the disease of the potato the cause is a deficiency of alkaline bases. This is manifest in the want of power in the cellular substance to perform its office, and it is also manifest in the presence of acid in the potato.

In consequence of this deficiency of alkaline substances, the potato plant forms an alkali peculiar to itself, which is very poisonous in its nature; and which, I doubt not, produces the fatal effect sometimes consequent upon eating the diseased potato.

If this theory be correct, the proper remedy is to supply the alkaline substances, such as lime, good strong ashes or soda, one or more of them; and not use quite so much or so rich manure as is commonly used.

Chemico.

Honesdale, *Pa.*

For the Farmers' Cabinet.

THE POTATO ROT.

Mr. Editor: Any information on the subject of the rot in the potato that even approximates to the truth is much needed at present. I hope you will not consider a column of your paper unworthily filled which contains a communication devoted to that object.

I stated in your May number that the rot in the potato was caused by a deficiency of alkaline substances. It is found, by burning the tops of the potato, that 10,000 parts yield 1,500 parts of ashes, while oak wood in equal quantity yields only 250 parts. This will serve to show the great quantity of alkali contained in potatoes over other vegetable matter.

The cellular tissue of all vegetables is composed partly of alkalies. They exist therein in a variety of forms; sometimes as carbonate of lime, at others as silicate of potash, at others in the form of phosphate of lime, &c. &c.

It is plain that if a plant has not sufficient alkali for the formation of the cellular tissue, its growth will be impeded, or the cellular substance will be so weak and thin as not to be able to perform its function of holding the starch and other matter contained in the potato. When the plant has not enough alkali, therefore, we may look for the cellular tissue to be broken and otherwise injured. This is actually the case with the potato that is affected with the rot. Mr. Teschemacher, a scientific gentleman of Boston, who has examined the rotten potato with a microscope, says "the cells appeared lacerated." This is what we would expect, especially when the substance contained in the cells is swollen by wet or heat, and the tissue is thin. In another place he says: "Indeed, it appears to me that the injury takes place by the rupturing of the cellular parts of the potato."

When the cells are ruptured the health of the potato is destroyed, and death and decay follow in the parts so ruptured. The decayed matter gives food to fungi and insects, and thus gives rise to the theory that the disease is caused by the fungi, or insects, instead of the want of alkali.

Again, when there is sufficient alkali to neutralize an acid, the acid is not to be found as such. It has entered into a chemical combination with the alkali, and assists in forming a salt. There is carbonic acid in a rotten potato, which is evidence that there is not alkali enough to operate upon it. If an alkali is placed upon some of the rotten potato, it instantly changes. Mr. Teschemacher says, in his letter to the New England Farmer, dated Boston, October, 1844, while speaking about his experiments—"A portion of the dark substance was placed upon a piece of glass on the microscope stand, in a drop of distilled water, and then thoroughly examined. A little salt on the fine point of a penknife was then added. A nearly instantaneous change took place. The dark colored masses separated; much of them seemed to pass away; and instead, there appeared numerous dark, slate colored globular bodies, which I easily recognised as the spores or reproducing bodies of the fungus. With the gray, slimy substance, the effect was still more striking. All the indistinct slime disappeared; the mass became clear and transparent, and left nothing but these innumerable dark globules floating about in the drop of water."

Salt is well known to be a muriate of soda. It appears evident, from Mr. Teschemacher's experiment, that the soda of the salt left the muriatic acid and entered into combination with the carbonic acid of the rotten mass, forming a carbonate of soda, and setting the muriatic acid free.

This carbonic acid is highly infectious, and hence the reason that a potato slightly rotten soon becomes wholly so, and infects those with which it is in contact. Any alkali will neutralize it, forming with it a carbonate. Consequently any alkali will cure the rot in the potato. This it will effect in two ways: First, by strengthening the cellular tissue, thus preventing the rupturing and consequent disorganization of the potato, which would result in death and decay; and, secondly, by neutralizing the carbonic acid, and thus destroying its infectious principle. [The writer here considers, and illustrates his views by, instances in the last report of the Commissioner of Patents. See T. Croft's letter.]

It is well known that poudrette, bone-dust, silicate of potash, and guano, contain one or more of the alkalies. I am disposed to think, Mr. Editor, that the above extracts prove conclusively the theory that the rot in the potato is caused by a want of the alkalies. At any rate, I should strongly

recommend their use. They can do no harm, unless abundantly used, and they may do an immense amount of good.

Yours, &c.,

CHEMICO.

HONESDALE, PA., *June* 6, 1845.

The foregoing we consider a valuable communication. Partly in corrobation of the views expressed, the editor recollects that in the use of lime on his farm there was no crop, unless perhaps it was the oat crop, on which that material had so uniformly a beneficial effect, as that of potatoes. The hints may easily be made use of, and at little expense.—EDITOR.

For the Farmers' Cabinet.

DISEASE OF THE POTATO.

MR. EDITOR: In perusing the last number of your paper, I noticed an article over the signature of Chemico, purporting to give a correct reason for the cause of the disease in potatoes, and also proposing a remedy.

It is a well known fact, that the disease in potatoes is of recent origin,* and it is also well known that the soil in which they grow contains the same quantity of alkali, and no less nitrogen than formerly. If a want of the alkalies, or a redundant supply of " nitrogenous matter," can be the only cause, then the disease might be confined to one district alone; but, observation, reports, and evidences, from well authenticated sources, affirm that the whole continent is alike affected: even in Europe the potatoes have not escaped the contagion. Lands which now yield but a poor and sickly crop of potatoes, a few years ago brought an abundant harvest. It has, furthermore, been ascertained by men of high professional repute that potatoes contain properties capable of accumulating the alkalies, and repelling a redundancy of nitrogen. Hence, it is easy to be seen that they are formed in such a peculiar way as to reject and throw off every substance detrimental to a vigorous and healthy growth.

Where, then, lies the true cause? It must be some uninvestigated agent, so powerful in its nature as to destroy the capability of the repulsive properties, and so poisonous in its effects as to paralyze the cellular organs, so as to prevent their performing their allotted task. Now, whatever may be the cause of the disease, it certainly cannot be the want or the redundancy of the above mentioned properties, to which Chemico attributes it.

I have noticed, particularly, that the first indications of the disease commence in the stalk; and, by an examination, I have found that the potatoes are fit for all culinary purposes, even when the stalk assumes a dark rotten color, and emits a putrid odor. As the disease follows down the stalk, the potato is at length affected, its health destroyed, and it becomes a useless vegetable. I have heard learned men say it is caused by an unusually large quantity of caloric coming in collision with a sudden and severe shower of rain; thereby creating a large quantity of hydrogen and sul-

---

*The recent origin of this disease is, we think, doubtful.—See the translation of a paper in the 7th No. of current vol. of Cabinet, page 212.—ED.

phuric acid gas. How far these doctrines are correct, I will not vouch; but suffice it to say, they seem to me plausible.

A Farmer.

Honesdale, Pa., *June* 2.

For the Farmers' Cabinet.

DISEASE OF THE POTATO.

Mr. Editor: In your last number I noticed a communication on the above subject, from this place, signed "Farmer."

The author of said communication seems to differ with me *in toto* in regard to the cause of the disease in question. He objects to my *reasoning** in the matter, and substitutes the *opinion* of some *learned men.*

After stating that the disease of the potato was of recent origin—by the way, Mr. Editor, your hint that this was doubtful was timely and proper, as we hear of the disease as far back at least as 1815, some thirty years ago—your correspondent, "Farmer," says "it is also well known that the soil in which potatoes grow contains the same quantity of alkali, and no less nitrogen than formerly. If a want of the alkalies or a redundant supply of nitrogenous matter can be the only cause,† then the disease might be confined to one district alone." I may be short-sighted, Mr. Editor, but I must confess I cannot see the *rationale* of this. I cannot for the life of me understand why "the disease might be confined to one district alone," unless that district should comprise nearly the whole earth, when the want of alkaline matter is so general.

"Farmer" lays it down as a "well known" fact, that "the soil in which potatoes grow contains the same quantity of alkali, and no less nitrogen than formerly." Now, however much I might be disposed to differ with "Farmer" in this matter, and say that when a soil has been deprived of a portion of its alkaline matter by taking off it large crops of hay, fodder, &c., and none or but little has been returned to it, it has less than it had before, I will, for the sake of making the subject clearer, omit doing so for the present. It is a "well known" fact, that all salts have a relative proportion of acids and alkalies. Therefore, notwithstanding the soil may have as much alkali now as it had formerly, still it does not follow, as a matter of course, that it has now a sufficiency. The soil formerly may have had enough alkali for the acid it contained at that time, but in consequence of the farmer supplying large quantities of manure, which produce an abundant supply of carbonic acid, the soil needs a greater supply of alkaline matter than it before contained, to form a salt by union with the extra quantum of carbonic acid. This is the main reason, in my opinion, that the rot in the potato is more general now than it was a few years ago. It has been the practice until recently to skin the soil as closely as possible, and supply but little manure; but since 1836, "a great change

---

* See page 316, current vol. of Cabinet. [See page 498, *ante.*]

†I did not say, Mr. Editor, that "a redundant supply of nitrogenous matter" was the cause of the disease of the potato; I said that "the substance forming the cells of all plants is a compound of nitrogenous (I should have said carboniferous) matter, with one or more of the alkalies, together with silex, &c. This has nothing to do with the cause of the disease of the patato, which, as I said before, was owing to a want of the alkalies.

has come over" agriculture, and farmers have been brought to think that they must give the soil something, while they are constantly taking away from it. They have since that time been throwing on large quantities of manure; and, not supplying proper proportions of alkaline matters, they find that diseases infest their plants, such as the rust in wheat, and the rot in the potato.

I must plead guilty to the charge that I am ignorant of the fact that "potatoes contain properties capable of accumulating the alkalies." The sentence in "Farmer's" communication containing this idea is very ambiguous to me; I do not understand it.

Again, he says, "it is easy to be seen that potatces are formed in such a peculiar way as to reject and throw off every substance detrimental to a vigorous and healthy growth." Not so easy to be seen, after all, Mr. "Farmer." If this was the case, how is it that the potato does not expel the "hydrogen and sulphuric acid gas," that "Farmer" seems to think is the cause of the disease? If they possess the power to reject and throw off every substance detrimental to a vigorous and healthy growth, how is it that they suffer the "hydrogen and sulphuric acid gas" to destroy their organism? It cannot be supposed that such destruction is one of the indicatives of a "healthy growth."

In regard to this matter of "hydrogen and sulphuric acid gas" being the cause of the disease of the potato, I have a few words to say. It strikes me that hydrogen cannot have anything to do with the disease; for if hydrogen be in contact with oxygen, the gas that *must be present* where decay is, they will unite and form water, and consequently the oxygen could not carry on the work of decay, and therefore the decay must stop. It seems more likely to me, after a few minutes' consideration of the subject, that the presence of hydrogen, so far from causing the decay of the potato, would have the effect of preventing it.

Respecting the other part of the theory of the "learned men" alluded to by "Farmer," that "sulphuric acid gas," thrown to the earth by those "sudden and severe showers of rain," is the cause of the widespread injury sustained by the potato, I would ask, what is there in the whole formula of chemicals that will destroy the effect of sulphuric acid in a more effectual manner than the very substances I propose for the prevention and cure of the rot in potatoes?

I am sorry that my communication is of so great length. I find that it requires fewer words to raise objections, than it does to answer them in a plain and explicit manner.

I should like to say more about the communication of "Farmer," particularly on the subject of the appearance of the stalks of the diseased potato. Their appearance justifies my idea of the cause of the rot, but I shall have to postpone it for the present.

CHEMICO.

HONESDALE, PA., *June* 19, 1845.

WILKESBARRE, LUZERNE COUNTY, PA.,
November 22, 1845.

DEAR SIR: The immense injury sustained from the "rot" by the potato crop of the United States, during this and former years, and the dis-

tress and alarm in Europe, at this time, caused principally by it, would seem to call upon every one who could say anything that seems at all reasonable of the cause and cure of that disease, to let himself be heard. With this conviction I address you this letter, wishing you to excuse the familiarity, and urging as my apology, if such apology be needed, the importance of the case.

And if you think I sustain my position, or establish, so far as a treatise of this kind could, the theory which I advance, you can so use this communication as to make it of service to the world at large, and thereby fulfil the intention of its author much better than he himself could.

I have abundant reason to believe that the "potato rot" is caused by a want of alkalies.

It would make this letter too lengthy were I to introduce *all* the evidence I have of the correctness of the theory I advance, and therefore I hope I shall be excused for ommitting a part of it. If, however, more is wanted, I am ready at any time to furnish it.

I will first speak of the theory of the disease. All plants, for a healthy growth, need certain elements *in certain proportions.* If more of one of these elements be given, by man or by nature, to the plant, than is proper to form a compound with the other elements, then the elements furnished are useless, if not injurious. I take some extracts from Dr. Liebig's great work on agricultural chemistry—one of the best works of the age on that science; the author of which is certainly entitled to full credit in his opinions, particularly when we have no evidences to the contrary.

The extracts are taken from the chapter on "the inorganic constituents of plants," and are as follows:

"Carbonic acid, water, and ammonia are necessary for the existence of plants, because they contain the elements from which their organs are formed; but other substances are likewise requisite for the formation of certain organs, destined for special functions peculiar to each family of plants. Plants obtain these substances from inorganic nature. In the ashes left after the incineration of plants, the same substances are found, although in a changed condition. Many of these inorganic constituents vary according to the soil in which the plants grow, but a certain number of them *are indispensable to their development.*" "Many plants, perhaps all of them, contain organic acids of very different composition and properties, *all of which are in combination with bases, such as potash, soda, lime, or magnesia.*" "But if these acids constantly exist in vegetables, and are necessary to their life, *which is incontestable*, it *is equally certain that some alkaline base is also indispensable in order to enter into combination with* the acids, *which are always found in the state of salts.*" "The perfect development of a plant is dependant on the presence of alkalies or alkaline earths; for when these substances are totally wanting, its growth will be arrested; and when they are only deficient, it must be impeded."

These extracts serve to show that alkaline matters are necessary for a healthy plant. Without stepping beyond the bounds of reason, we may well suppose that a plant which had not a proper supply of alkalies would be unhealthy; and when we consider the fact that carbonic acid is absorbed by all vegetable matter, and that *it is highly infectious when not neutralized*, causing decay where decay has not commenced, and assisting it after it has commenced, it appears to me the cause of the potato disease

may be very clearly seen. The cellular tissue of all vegetables is composed partly of alkalies. Hence, if the potato, for instance, has not sufficient alkali for a healthy growth, or, in other words, has not sufficient to enable it to assimilate all the carbonic acid it has absorbed, and thus form a strong cellular tissue, we may very naturally expect that such cellular tissue, if formed at all, will be very weak, and not able always properly to perform its functions. Such tissue, if anything occurs calculated to test its strength, will, we would suppose, be found, on examination with a good microscope, to be torn and ruptured. This it appears is actually the case with the diseased potato.

Mr. J. E. Teschemacher, a scientific gentleman of Boston, in a communication copied in your last report, on page 233, says, after examining the diseased potato with a microscope, that "many of these cells appeared lacerated." It is well known that water will cause vegetable matter to swell, and that heat will cause water to expand; hence if the cellular tissue be weak, and therefore not able to bear a strain, and the starch contained in the cells becomes swollen by water, *disorganization must inevitably follow*, more particularly so when that water is assisted by heat. As death and decay are the consequences of disorganization, the facts will explain why potatoes are so apt to rot during hot and wet weather. The cellular tissue may be weak; and yet if the weather be cool and dry, and as a consequence no strain comes upon it, that weakness may not essentially injure the potato; but if the weather becomes hot and wet, the cellular tissue must give way, and allow disease to do its work. This decay, however, may be stopped by the aid of the alkalies, even after disorganization has taken place. For evidence of this fact I refer you to the communication of Mr. John S. Netterville, published on page 229, in your last report, where he says: "But about the middle of December my family complained of the bad smell in the cellar; upon which I examined, and found the potatoes in a bad condition, and I took them out of the bin and picked them over again, and when returning them into the bin, in every layer I put about half a peck of slacked lime and mixed it well through them, and so on till all was in, which I do believe stopped the rot and bad smell, as there were but very few found affected afterward."

It would seem from the above statement that the carbonic acid, which is the product of decay, and which is, as I have before said, highly infectious, loses this power when lime is present; this is occasioned by the neutralizing effect of the lime, which forms with the carbonic acid a carbonate of lime, which is a salt. Berthier, in his "*Annales de Chimie et de Physique*," *tome* XXX, *page* 248, says: "10,000 parts of oak wood yield 250 parts of ashes; the same quantity of fir wood only 83; of linden wood, 500; of rye, 440; and of the herb of the potato plant, 1,500." It will thus be seen that the herb of the potato plant contains six times as much ashes as oak wood. Dr. Lee, a scientific gentleman of New York, who is at present, I believe, engaged by the New York State Agricultural Society to visit every county in that State and deliver lectures on agricultural chemistry, in a letter to the editor of the Albany Cultivator, from "Smithville, Chenango county, New York," dated July 15, 1845, and published in the August number of the Albany Cultivator, says: "More than one-half of the ashes of potatoes is pure potash." As every thing contained in a plant must be furnished by man or by nature, this will serve to show the necessity of

using *more potash* in the culture of potatoes than on any other crop; particularly if there be none of it already in the soil. Dr. Lee, in the letter already referred to, says: "A sugar maple, a grape vine, an apple tree, and a potato plant, *need a soil that* ABOUNDS IN POTASH."

Take from your fields 200 bushels of potatoes this fall, and you will remove from it sixty-three pounds of this mineral. One bushel of ashes are said, by those who have used them, to make *ten extra bushels of potatoes.*

If, therefore, potash be not present in sufficient quantities, we may reasonably expect that the potato will be impeded in its growth, if indeed that growth is not totally arrested. If, while the growth is impeded, the supply of carbonic acid be great, and the potato has an opportunity of absorbing it, such carbonic acid will, by its infectious properties, (even if there be a comparative drought at the time) disease the potato; and if such disease be not checked, it will totally destroy the potato. Carbonic acid loses this infectious property when it becomes a salt, by union with an alkali, and is then rather beneficial than injurious; for, if that alkali be *potash*, the potato plant will assimilate both the potash and the carbonic acid; and other conditions being equal, the result will be a large and *healthy* growth.

The foregoing remarks would lead us to suppose that by supplying the alkalies in sufficient quantities we would at least save our potatoes from the "*rot.*" Let us see if we can find any evidence to sustain us in that theory. If we cannot, but on the contrary find evidence against it, we should abandon it at once; but if we cannot find any thing against it, and all the evidence upon it is in its favor, it is certainly worthy of our attention.

If I had time, (unfortunately I am a poor man, and therefore have very little of that to spare,) and would take the trouble, I could give you the written certificates of several hundred men, who, when they have used alkaline substances in sufficient quantities upon their potato crops, *have never yet lost a crop by* "*rot;*" but, as such certificates would not be so satisfactory as some other evidence I am about to give, I will save myself the time and trouble of procuring them.

The first evidence I will offer is that of Dr. Lee, before mentioned. In the letter of this gentleman, from which I have already taken two extracts, I find the following: "More than one-half of the ash of potatoes is pure potash. Acting on this hint, I have found in my tour scientific farmers, who, by the use of unleached ashes, lime, and plaster, mixed in equal parts, and placed *in the hill* with the seed, *and on the hill* as soon as the tops have well grown, *have wholly escaped the potato rot, and harvested for several years from* 500 *to* 600 *bushels per acre.*" This would seem to be evidence enough to prove that experience sustains my theory. But I have more to offer: On the 88th page of your last report as Commissioner of Patents, it is stated, as coming under your own observation, that a composition containing an alkali (lime) had prevented the rot. It is also stated on the same page, that to prevent the disease, "salt, lime, and plaster" (all containing alkalies) "have been respectively recommended by their advocates, and in some instances with diverse success;" but, after several close examinations of your report, I can find nothing *there* which will go to show that substances containing alkalies, *when properly applied*, *have ever failed of* HAVING FULL AND COMPLETE SUCCESS IN PREVENTING THE ROT. On the other hand, I find considerable evidence going to sustain an opposite view of the case. Permit me to mention some of it. On the 224th page you will find the following, being a part of a letter from a Mr. S. F.

Perley, a correspondent of the Massachusetts Ploughman, who dates his letter October 17, 1844. He says: "The rot has prevailed most in ground highly dressed with barn-yard manure, especially if placed in the hill. When potatoes were planted without any manure, they have rotted very little. Two pieces on similar ground, (rather wet,) the one manured from the barn, the other with hair, *lime*, fleshings, &c., from the tannery—both applied in the hill—the first rotted badly, the other very little. Two pieces —the first dressed broadcast, and in the hill, from the barn; the other broadcast, with a compost of barn manure and swamp muck, muck *and ashes*, and clear manure—both dry; the first was planted early, the latter late:—the first rotted in the field; and, being dug in the hot weeks in September, rotted after being put into the cellar; while the latter, dug at odd jobs, from the middle of September to the middle of October, suffered very little. This piece had plaster put on at the time of planting, and after the potatoes were up."

It would appear from the above that the manure which had been applied had been the principal cause of the rot, as "when the potatoes were planted without any manure they had rotted very little."

This is accounted for by the fact that the manure furnished the destroying agent, the infectious carbonic acid. On pages 230 and 231, it is related that a Mr. Minor, of New York, stated to the New York Farmers' Club, at their meeting on November 12, 1844, that Mr. James Hay, of Westchester, had informed him "that his potatoes raised with farm-yard manure this season were diseased, so that he threw away 20 per cent. of them; that on land where he had used concentrated manure, he had good potatoes." Mr. Minor states that this concentrated manure is poudrette, which, you are no doubt aware, contains one or more of the alkalies.

On page 237, Dr. Jackson, in a letter written to the Albany Cultivator, dated September 23, 1844, says: "I learned that where lime had been used in a preparation of about a table-spoonful to a hill, there no disease has appeared;" and on page 244, a Dr. Gardiner is represented to say that "Mr. Anderson has tried lime broadcast; his crop is good." I could refer you to more evidence of this kind, but it might be urged as an objection that these were coincidences—that it merely "*happened*" that where these alkalies were applied the crop "*happened*" to be good; or that the soils were different, or something of that sort. To silence such objections as these, I will now show that in the same field—of the same soil—during the same season—with the same heat—the same droughts—the same wet weather—the same seed—the same exposure to fungi and to insects, (see an article on "*Fungi and Insects*," over the signature of "Chemico," in the October number of the *Farmers' Cabinet*, Philadelphia, Pa.,) with the same culture, and with all other circumstances similar—where the potato crop was supplied with substances containing alkalies, *it was saved from the rot*; and where it was not, *it signally failed*. Before doing so, however, allow me to introduce a few statements going to show the truth of part of the foregoing premises, although they do not sustain all, as some others do that I will, before concluding this article, call your attention to.

The first case I will refer to is that related by the president of the New York Farmers' Club, at the meeting I have before mentioned, which you will find recorded on page 232 of your report. It is as follows: "On our farm last year we tried potatoes where lime had been put the year before, at the rate of sixty bushels to the acre; it was on a part of our garden,

which was also well manured at that time. Another trial was made on a field which had been well manured; sheep had run upon it; *both the field and the garden are old, high, and loamy land.* No lime was put on the field. The potatoes in the garden were planted in April, and dug up in August; *they were perfect.* In the sheep field the potatoes were planted in the last of May or beginning of June, *and we hardly had our seed potatoes restored to us.*"

The next case I will mention is that of Mr. J. S. Netterville, who writes from Palatine bridge, Montgomery county, New Jersey, to the editors of the Boston Cultivator, and whose letter is copied into your last report, page 229, where he says: "This spring, when I began to plant my potatoes, I took about a table-spoonful of slacked lime and put it into each hill; and when they were up, and *before they were hoed*, I made a mixture of eight bushels of leached ashes, two bushels of lime, and three bushels of ground plaster, and stirred them well together. I made a scoop that held about one gill, and I put this full of the mixture on each hill, close to the stalks, and I found, when I began to use them in the summer, *that they were all sound and continued so; and I had not one rotten potato when I took them up in October, although my neighbors on both sides of the farm had scarce any sound ones to get in; so I must think that what I did to my potatoes was the cause of my being so successful.*"

The above is somewhat conclusive, but the following is still more so. On page 264, a Mr. Joseph Walton, writing to the editor of the Albany Cultivator from St. Andrews, New Brunswick, and whose letter is dated November 20, 1844, says: "*Mr. Editor:* I notice in the November number of the Cultivator complaints made about the 'rot' in potatoes. *I was troubled with it for many years, and having found a remedy, give it for the benefit of your readers.* The rot in potatoes in this section of the country commenced about ten years ago; one-third of a crop was frequently lost by it, and often in the spring hundreds of bushels have been thrown from the cellar quite useless. For some years past I have used slacked lime, which I sprinkle on the potatoes as soon as they are cut for seed, and shovel them over in it, and plant them immediately. *Since I have adopted this plan I have not lost a potato, either in the ground or after they were put in the cellar; and such of my neighbors as follow my example are alike fortunate, and in no way troubled with the rot.*"

But the most conclusive experiment, and the one that demonstrates the truth of what I said in my promise (given in this article) beyond all doubt or quibble, is one made by Mr. R. L. Pell, of Pelham farm, Ulster county, New York; a statement which is made in a letter written by him to yourself, dated December 18, 1844, and published on pages 241, 242, and 243, of your last report. In that letter he says: "In the year 1843, I planted a field of several acres in drills, harrowed the ground level, and top-dressed it with 200 bushels of oyster-shell lime and charcoal dust to the acre. The yield was 432 bushels per acre. *At the same time, the potatoes throughout the country were more or less decayed; likewise a parcel of the same seed, planted contiguous to the above, not limed, was also decayed.* This year (1844) I planted the same seed in the following manner: The ground was thrown into drills and manured heavily with barn yard manure. The potatoes were cut into single eyes fourteen days before required for planting, and covered with plaster. Limed a few for the sake of experiments specified. They were sprinkled with small white (almost imperceptible) insects,

and were consequently rejected. Those limed were free. I planted them in the drills on the manure, nine inches apart; tops, centres, and ends separately, to mark the difference in growth, which was very great. The first three drills (300 feet in length) were covered with dry charcoal dust.

"No. 2.	Three drills	covered with	oyster-shell lime.
No. 3.	Do	do	bone-dust.
No. 4.	Do	do	poudrette.
No. 5.	Do	do	unleached ashes.
No. 6.	Do	do	new mown grass and plaster.
No. 7.	Do	do	fine salt.
No. 8.	Do	do	silicate of potash.
No. 9.	Do	do	guano.

"And so on throughout the field, each alternate three drills with a different substance, except six drills, in which the same seed was planted without any composition except the barn-yard manure; and adjoining them six drills, planted with superior French potatoes, received, three weeks before, directly from Havre. The furrows were then all reversed by the plough and the potatoes covered, after which a heavy stick was drawn by a pair of horses across the furrows to level them.

"No. 1.	The potatoes	planted in	the first three drills came up first.
No. 6.	Do	do	with new mown grass and plaster, second.
No. 8.	Do	do	with silicate of potash, third.
No. 9.	Do	do	with guano, fourth.
No. 3.	Do	do	with bone-dust, fifth.
No. 4.	Do	do	with poudrette, sixth.
No. 7.	Do	do	with fine salt, seventh.
No. 5.	Do	do	with unleached ashes, eighth.
No. 2.	Do	do	with oyster-shell lime, ninth.

The 12 drills without composition came up later than any of the rest.

"*Cultivation.*—When they were four inches above ground the earth was ploughed from them. After an interval of six days it was ploughed to them again; the field being in perfect order, required no other attention during the season. On the 3d of October they were ploughed out, and *proved to be perfectly sound, with the exception of the twelve drills of pink-eyed kidneys, and French potatoes, without composition, which were entirely rotten.* 600 bushels were pitted immediately, and not examined before the 5th of December, when they were found to be perfectly sound."

It is known to yourself, that in guano, silicate of potash, salt, plaster, unleached ashes, poudrette, bone dust, and oyster-shell lime, there are alkalies. In some of these substances there are several of them—in others but a few. The charcoal dust, mentioned as having been used successfully in Mr. Pell's experiment, *prevented the potato rot by virtue of its well known powers of absorbing carbonic acid, and thus preventing the potatoes from absorbing it to their injury.*

Thus we see that the theory I advance, besides being reasonable and based on a knowledge of the chemical nature of the plant, is proved by numerous and definite experiments that are well attested, so that but little doubt can exist of its truth.

If, then, this be the case—and it appears to me no reasonable man can doubt it—how easy is the cure of the disease of the potato effected! No

need of the trouble and expense of sending to South America, or any where else, for a new stock; no need of raising potatoes from the balls for the purpose of getting a more hardy variety, or one more capable of resisting the disease; no need of sustaining great losses from the rot; no need of planting out of season; no need of fearing the effects of the fungi; no need of dreading the attacks of insects; no need of giving up the raising of potatoes on account of the unprofitableness of the crop, when that unprofitableness results from the failure of it on account of the rot; no need of gloomy fears of starvation, and all its accompanying evils; no need, I say, of all these. All that will be necessary is, for each potato raiser to gather a few stones from off his farm and make him a snug little ash-house, that will not be liable to take fire, and that will keep out the wet, and then let him require his family to put all their ashes in *there;* and when he plants his potatoes, put those ashes on them, and manure them with rotten straw, hay, sawdust, or swamp muck, and not with stable or animal manure. And if he finds in the fall, or the latter part of summer, that he has not put enough on—that, in consequence, his potatoes are diseased—let him lose no time, but take a bag full of the best ashes he has, and, throwing it on his shoulder, go over his potato patch and sow it on them till they look light with the dust; it is better that this should be done in the morning before the dew is off, or during a slight shower, but any time is better than neglecting it altogether. By so doing, his crop will be large, and the potatoes will be healthy and in nowise affected with the rot.

If you desire other information on this subject, see several communications, over the signature of "*Chemico,*" in the May, June, and October numbers of the "*Farmers' Cabinet,*" an agricultural journal published at Philadelphia, in this State. The communications are severally headed "Disease of the potato;" "Potato rot;" "Fungi, insects, &c.—how to prevent their attacks on plants."

Wishing you health and prosperity for your many and well-directed efforts for the advancement of science, and particularly in agriculture, and your labors in the cause of home industry, permit me to subscribe myself yours, with the most ardent desire for the advancement of mankind in knowledge and happiness,

THOS. CROFT.

Hon. H. L. Ellsworth.

From the Albany Cultivator.

DISEASE IN POTATOES.

From several sections we hear there are already symptoms of this disease. B. P. Johnson, esq., of Rome, writes us, July 18th—

"I have examined, within the last few days, a number of fields, and find indications of the disease in almost every field. The upper leaves first show indications of the disease—the leaves shrivel or curl up, and it soon extends to the entire stalk. In some instances, when the potatoes have been dug, on cutting them open a small black spot is found in the centre. In others the potato appears sound and healthy.

"The disease is not confined, so far as my observations extend, to any particular variety of potato, or to any special location. Seed procured from

the west, where no defect was apparent last year, suffers equally with seed selected from the crop raised in this section last year. I planted some this year, and made a preparation of salt, plaster, and house ashes, of nearly equal quantities, though of ashes the most, and put about a handful in each hill before covering. The vines look remarkably well, and as yet are free from the curl in the leaves. Whether they will escape, a few days will determine.

"I am led to believe that this disease is somewhat analogous to smut in wheat. As it has made its appearance so early in the season, I hope careful observations will be made, in order, if possible, to aim at some definite conclusions in relation to the cause of the disease and remedy."

Dr. Camp, of Windham, Greene county, has sent us a couple of insects, of a kind which he thinks causes the rot in potatoes. He states that the blight which precedes the rot has already attacked the crop, and that on all the affected stalks he finds more or less of these insects. The healthy vines, he states, have no insects on them.

For the Boston Cultivator.

ROT IN POTATOES.

Messrs. Editors: The common disease of last year has again made its appearance among the potatoes in this section of the country; to what extent the malady is prevailing, is not exactly known. Now, I am inclined to believe that the disease is chiefly caused by the atmosphere operating upon the stalk in such a manner as to obstruct its natural circulation of sap, which prevents the regular exhalations of the plant, and deranges nature's perfect operations by preventing the escape of the excess of ammonia which accumulates in the hill, and is held there in a state of unnatural confinement by the disease of the stalk and the crust which forms upon the surface of the ground, which makes the hill nearly air-tight. Then, the ammonia in the hill engenders disease, which usually, under these circumstances, makes its appearance in the form of a blister upon the skin, and soon makes progress towards the heart or middle of the potato, forming, as the disease progresses, a kind of fungus upon the surface of the tuber.

In other cases the ground appears to crack near the root of the vine, so that the ammonia escapes so rapid that the vine is killed at once; in which case, it is not uncommon to trace the disease directly down from the stalk, in black streaks, to the middle of the tuber.

The reasons which have led me to the foregoing conclusions are many and various; a few only of which will be here suggested, with the hope that others more close in observation, and more philosophical in thought, will show my mistake (if I am in error) by tracing out the true cause of the malady, and prescribe a remedy. In the first place, then, my own observations, corroborated by the testimony of hundreds of others, show very clearly that when the land is manured with that kind of manure that is highly charged with ammonia, the malady is most fatal. 2d. Where the same land, side by side, is manured with manure so rotted as to have lost all its smell, very little disease is found. 3d. The hardiest varieties of potatoes are not as liable to the disease as those which are more tender and feeble. 4th. That kind of compost possessing no smell of ammonia will

invigorate the stalk and elude the disease: for instance, proudrette, salt, lime, house ashes, plaster, &c. It is believed that an entire revolution in the mode of cultivation must take place, before the farmer will be as certain of success as formerly. Manure that is in a state of fermentation when applied to the potato hill, or manure that will ferment so as to exhale ammonia to any considerable extent during the growth of the plant, will be likely to engender disease, unless some compost or other substance is used, which will so strengthen and invigorate the stalk as to enable it to elaborate the sap, and convey back from the air to the root those nutritive elements so necessary to the hill, in order to preserve the health of the family of tubers contained therein.

Unless some substitute is used for manure that will not promote ammonia in the hill, what must the cultivator expect? Disease or disappointment; or he must select poor land for raising his potatoes, and be content with small crops. We suffered greatly by the malady last year, and at that time had no precious experience in the matter. This season we have taken a different course in the preparation of our potato lands. Instead of using any manure, we selected land that was highly dunged last year from the sheep pens and cattle stables, and was in corn. Ploughed twice, as usual, aad planted early in May, three feet apart both ways; we cut the potatoes, and used as much lime as would stick without water. As soon as the plants were out of the ground sufficiently to live, we made a compost of salt, unleached ashes, lime, and plaster; incorporated the whole together, and top-dressed every hill with a table-spoonful of the compost, and covered it in the hill at hoeing—hoed twice. After the potatoes had gone out of blossom and the hot weather set in, in July we sowed broadcast over the field two bushels of salt to the acre. These potatoes have been in eating three or four weeks, and not a diseased potato can be found in the whole field.

Respectfully yours,

J. M. WEEKS.

Salisbury, Vt., *September* 1, 1845.

From the Kennebec Journal.

CROPS AND WEATHER.

The potato rot, which, for two or three years, has been so destructive in the middle States, and last year in Massachusetts, and to some extent in New Hampshire and Maine, appears to spread this year over all New England, Nova Scotia, and New Brunswick. Some few locations may escape with little damage, but the destruction is very widely spread. In Somerset and Franklin thousands of acres have been planted in potatoes for the starch factories.

For the Boston Cultivator.

THE POTATO CROP IN MAINE.

Messrs. Editors: From what can be learned, this staple article, in this State, will, in consequence of the rot, fall short one-half or two thirds of a usual yield.

It will be a severe calamity to us, and to citizens of other States who have their supply of this useful and necessary article of food from this State.

In 1844 the farmers of this State raised 12,304,000 bushels of potatoes, and no State in the Union exceeded her in the business, excepting the great State of New York with her three millions of inhabitants. She raised 17,703,000 bushels—about six bushels to every person in the State; whilst Maine averaged about twenty-four bushels to every person in the State.

If we base our calculations upon last year's yield in Maine, the loss in consequence of the rot cannot be less than $1,230,400; more than two dollars to every person in the State.

The rot prevails generally throughout the State; last year it prevailed in some sections only. It then seized the potatoes about the last of August. It will be remembered that we had in this section of the State very warm weather, with frequent though not heavy rains, about that time, and it invariably cleared off very warm, when formerly it generally came off cooler immediately after rains.

This season has been the warmest for many years. The rains in this section commenced one month earlier than last year—say the last of July and first of August; consequently the most of potatoes, exceping those planted very early, and of an early kind, were young and tender when these rains commenced. The soil being heated by many days and *nights* of sultry weather, actually scalded them, and but few, if any, escaped, excepting early planted, and not even these when planted on unfermented manure.

It will be remembered that though we had frequent rains, they were not heavy ones—barely enough to wet the manure in the hill; which doubtless caused them to rot more rapidly than if the rains had wet down deeper. It will be remembered, also, that the sun came out very hot after these rains, killing the vines of the potato, whilst the heat and wet under the surface were doing their work of destruction to the young and tender tuber. The first appearance of the rot is dirty, yellowish spots, similar in appearance to iron rust; it penetrates the potato, and in a short time turns to a dark color, and the work of destruction is soon finished. They appear to smell and taste similar to a frost-bitten potato.

The State of Massachusetts will probably be exempt from this potato disease, if disease it may be called, as she was not visited by rains about the time it was so extremely hot; but her crop of potatoes must necessarily be light.

GEO. M. FREEMAN.

YORK, ME., *September* 25, 1845.

Editorial remarks.—The rot in the potato has prevailed in this State to a very small extent, compared to its effects in Maine and on the sea-coast of New Hampshire, where in many cases no more than a tenth part of a usual crop will be obtained. In some sections in this State the rot has not prevailed at all this year; yet owing to hot, dry weather, the crop is very light and the quality poor. Col. Sheldon, of Wilmington, informs us that he usually gets about 200 bushels of potatoes to the acre; that this season he had only about 700 bushels on 14 acres. Potatoes in general are of a poor quality this year. They are brought into this market from different States,

and from Nova Scotia and New Brunswick, and they are most all poor—watery, heavy, and of poor flavor.

From the Newark Daily Advertiser.

THE POTATO ROT IN NEW JERSEY.

We learn by the Burlington Gazette that Nathan Stowell, of that place, has been directing his attention for four years past to the subject of rot in the potato, in hopes of discovering the cause of a disease which begins to threaten very serious consequences. Mr. Stowell thinks the rot is owing to the sound seed having all run out, and that too little new seed has been produced. He has himself produced a fine crop of new potatoes from tubers of the Foxite variety, and out of nearly fifty bushels not a single potato is diseased. The vines were free from blight. A patch of Mercers, close by, were grievously afflicted with the rot.

From the Saturday Courier.

THE POTATO DISEASE.

Messrs. M'Maken & Holden:

As much has been said and written of the disease of the potato, I will here briefly state my own plan and opinion in regard to raising them the past season. I planted them as soon as the ground would admit of it—manured them in the hill, with well rotted manure. In planting, I selected the largest, and was careful not to get any but those that were perfectly sound; kept the ground free from weeds till autumn, and dug them about the middle of October, although the tops were dead a month sooner. I thought it best to let them remain, and I can truly say that my expectations were more than realized, inasmuch as I had about 300 bushels to the acre, and have not seen one potato rotten, or in the least affected. At the same time my neighbors complain of their potatoes rotting, and many have had to carry them from their cellars.

Yours, &c.,

D. S. SANDERSON.

CHESTERFIELD, N. H., *November* 17, 1845.

ANOTHER CAUSE FOR THE POTATO ROT PROPOSED.

To the Editor of the Maine Farmer:

DEAR SIR: Please to inform your readers that, in my opinion, the failure of the potato crop by rot and rust is caused by cutting the seed. I think the whole trouble may be safely attributed to the unfortunate use of the knife among the seed designed for planting. I do earnestly entreat my agricultural friends to pause and take into consideration this hint before they complete the destruction of that valuable root. That beautiful skin

which God has put over the potato should not be cut, nor in any way wounded, if a perfect crop is wanted.

The reasons, if reasons are wanted to establish a self-evident fact, together with the remedy, can be made the subject of another communication, if desired. B. SHAW.

OLDTOWN, *September* 11, 1845.

Note.—We publish friend Shaw's remarks on the potato rot, although we cannot agree with him. If cutting potatoes caused the rot, why have we not been troubled with the disease years ago? The custom of cutting potatoes is old, while the rot is new.—EDITOR.

POTATO ROT.

To the Editor of the New England Farmer:

I observe in European newspapers, recently arrived, that the French Academy of Arts and Sciences deputed Mr. Charles Morren, of Liege, to examine into the cause of the potato rot. That the French should have selected a foreigner for this purpose, says more for the high esteem in which his talents are held, than anything which can emanate from me.

This gentleman has stated the result of his investigation to be, that the rot is caused by a *fungus*, the spores or seeds of which exist in vast quantities in the atmosphere; and this opinion has been generally received as true by the best informed circles in Europe. I have not seen the paper by Professor Morren, and therefore do not know whether he suggests any remedy or not. You well remember that the result of my observations on this disease, published in your paper last year, perfectly accords with that of Professor Morren, and that the remedy I proposed—of *salt*—was founded on the power of this substance to dissolve and destroy most of the fungus family; hence, where there was salt, the spores could not vegetate. I also regretted (and much more regret now, as the disease has caused such extensive devastation) that I did not possess a microscope of sufficient perfection to enable me to pursue my examinations both into the disease and its remedy; the want of this alone made me drop all further investigations on the subject. But previous to this, I repeated and considerably extended my experiments with various chemical salts, and drew up a paper of several closely written pages, containing the details, with all my views on the subject; which paper, by request, I sent to the New York State Agricultural Society, last December. Of this communication, as well as of one accompanied by eight or nine samples of various qualities of guano, with the analysis of each, they did me the honor *not to take the slightest notice.* I am very sorry that I did not keep a copy of this paper, which, of course, is now amongst things lost or forgotten.

I have no doubt that this disease is completely under the dominion of science, and that a perfect remedy for it exists.

Yours, truly, J. E. TESCHEMACHER.

BOSTON, *October* 4, 1845.

From the New England Farmer.

THE POTATO DISEASE—SALT AS A REMEDY.

Mr. Joseph Breck: I think the public must have reason to be satisfied with the indefatigable spirit you evince in collecting information on the subject of the potato rot, which is more universal in this country than most people think. I hear, every day, of instances of parcels stored in cellars, apparently sound when put in, which are now totally worthless. Depend upon it, unless some remedy be found, it will hardly be worth while to plant potatoes another year.

In order that I may not be misunderstood, I will now succinctly state my opinions on this subject.

I think that salt, lime, and several chemical compounds, will destroy the disease. I prefer salt, because, when mixed in the soil, it may get into the juices, and circulate through the whole plant. Lime, or lime-water, would do the same, to a certain extent, but it is far less soluble than salt.

The fungus I have seen vegetates upon and thickens the sides of the cells of which the potato is composed, which cells contain the grains of starch. The starch is not injured until the sides of the cells rotted by the fungus burst; the worms or maggots breed, and the whole finally becomes a mass of putridity, with an offensive, fungus-like smell.

I saw in your last week's paper several cases of the disease occurring where sea-weed has been used, and also near the sea shore. These cases would seem to militate against the idea of salt being a cure. But they are very far from convincing me, for the following reasons: the salt atmosphere near the sea may not have contained one-tenth enough salt to destroy the rot, or the prevailing winds there may not have spread the spray in sufficient quantity. And with respect to sea-weed: in a late London journal there are analyses of four different kinds of sea-weed, performed by burning the weed and analyzing the ashes.

			Ashes.	Salt.
Laminaria saccharina	gave to 100 lbs. about	-	10 lbs.	3 lbs.
Fucus vesiculosus	" 100 " "	-	20½ "	6½ "
Fucus serratus	" 100 " "	-	26 "	10 "
Fucus crispus, or Chondria crispa	" 100 " "	-	25½ "	4¾ "

They varied also considerably in the other ingredients. Now, when this great difference exists in the quantity of salt in different sea-weeds just taken from the sea, and when it is considered that the sea weed is often made into a compost, turned over and exposed to all kinds of weather, by which salt may be washed out, it must be obvious that no true judgment can be formed of its effects on the potato disease, unless the kind of sea-weed, and all the attendant circumstances, be taken into account. The spores of the fungus, in the cases alluded to, might have been, and most probably were, so numerous, that the salt thus adventitiously obtained was not sufficient to destroy them.

In a paper transmitted to the New York State Agricultural Society, (alluded to in a former communication,) I recommended an analysis of sound potatoes, and a parallel one of those just contaminated by the rot; and this to be done not in the usual way, by reducing to ashes, but by expressing the juices and analyzing *them*. This would show whether there was any difference in the ingredients that might be considered as offering favorable circumstances for fungus vegetation. The analysis by incineration should

also be tried; for, if salt destroys the fungus, as my own eyes as well as those of others have seen, it is a fair presumption that if we can get a solution of salt into the juices of the plant, in any shape, it will be unfavorable to the vegetation of the spores.

Until I see a number of experiments fairly tried with salt, lime, &c., and *they have failed*, I shall not be persuaded that the views I have taken of these, as remedies for the potato evil, are erroneous; and should they prove of no value, I am quite ready to give them up and *try again*.

Yours, truly, J. E. TESCHEMACHER.

BOSTON, *November* 15, 1845.

In our next, we shall, by request, give a translation of the opinions of M. Morren, Professor of Agriculture in the University of Liege, Brussels, whose investigations have led him to believe, with Mr. Teschemacher, that fungus is the cause of the potato evil—an opinion which is now attracting more attention from the intelligent classes in Europe, than any other yet advanced concerning the origin of the rot or murrain.—EDITOR.

[For Prof. Morren's, see appendix No. 6.]

BOSTON, *December* 8, 1845.

DEAR SIR: The steamer Cambria, just arrived, has put us in possession of the report to the British government by Professors Kane, Playfair, and Lindley, on the potato disease. We have now the reports, on this subject, of scientific men in three European countries: Professor Kutzing, in Germany, Professor Ch. Morren, in Belgium and France, and the above report in Great Britain. Having interested myself in this disease, by about three months' study last autumn, I have read these with some attention; and thinking a short review of them may lead to some useful conclusions, I address you according to promise—premising, however, that I shall leave nearly untouched the subject of saving potatoes for this year's consumption, or the more intricate process of starch making.

All these reports appear to coincide in the opinion, that a minute fungus is the first *visible* cause of the disease; that this fungus spreads rapidly through the tuber by means of its spawn, *mycelium*, or spores, causing rottenness. Professor Morren states that he has traced it from the leaf, where it commences, downwards, causing thereby the death of the haulm, from which it finally enters the potato. This is also my opinion, published in 1844. I had traced it through the place where the stem joins the tuber, not having commenced my investigation with the green haulm. But I had also seen it pass through the skin of the tuber, and work its way to the centre and all around. The British professors, doubting whether this fungus is the true cause of the disease, state, "that it seems to be connected with the cold, cloudy, ungenial weather which has characterized the present year over the north of Europe; conditions highly unsuited to the constitution of a plant which, like the potato, is a native of a warm sunny country, and insufficient for the ripening of the tubers.

But quite decisive objections to this view are—

First. That we have had a warm, dry summer on this side of the Atlantic, with more than a usual proportion of sunshine, and yet the disease has spread with equal fatality here; and,

Second. That they have had many such cloudy, wet, and cold summers

before in Europe, without the appearance of this peculiar disease in the potato.

It is clear, therefore, that this so called atmospheric influence is merely a name, without a distinct tangible meaning, and the evil of accounting for the disease by a mere name, such as an epidemic or atmospheric influence, is to stop all further inquiry and investigation, either into cause or remedy; for if the *nature* of the cause be not known, the attempts at remedy are mere guesses. If the seed of the fungi were not there, the atmospheric influence could not cause them to vegetate; and if, knowing the nature of this fungi, we can destroy them or prevent them from vegetating, there is an end of the disease. Again: that the disease has increased immensely since 1844 gives a very strong natural presumption that it arises from the rapid and more widely diffused propagation of a vegetable fungus, whose seed, (spores,) according to Professor Morren, are quickly generated in inconceivable numbers.

The British professors practically feel, however, that the disease is caused by this fungus, for they recommend "that potatoes should not be planted in the same soil from which the diseased ones are taken this year, as it is in all probability filled with the seeds of fungi, in countless myriads, which must have been scattered over the tainted fields, and, although they have been probably borne by the winds to every part of the country, are in great profusion there."

They must therefore clearly think that the spores of the fungi will again attack the potato. Any one with a good microscope can clearly trace the propagation of this fungus inside the sound potato, from cell to cell. It is on the sides (walls) of the cell that it vegetates; but they cannot trace any previous rottenness in the cells, although the juices therein may be favorable to this fungus propagation. A careful analysis of these juices, compared with those of perfectly sound potatoes, might throw light upon this subject. The increase and propagation of other vegetables as well as fungi, under peculiar and favorable circumstances, on which science has as yet but little knowledge, is not uncommon. A few years since, about 1½ mile square of salt marsh in East Boston, close to my residence, was one season entirely and thickly covered with *gnaphalium polycephalum*, scenting all around with its peculiar odor, where, for years previously, only a few spikes had been known, and to which state the spot has now reverted. It would be difficult to find a hundred spikes, where, that year, there were millions.

That there are peculiar circumstances which favor the rapid propagation of particular fungi is certain, and equally certain that there must also be circumstances unfavorable to it, and it is to the study and production of these unfavorable circumstances that we have to look for remedies.

A careful perusal of these reports will, I think, satisfy any one that a minute fungus, propagating profusely under favorable circumstances, is the cause of the disease; and that salt, lime, and various chemical salts, will probably if not certainly prove the most effectual remedies; and this is precisely the opinion I formed after about three months' investigation, during the autumn of 1844, and which I embodied in a paper I then sent to the New York State Agricultural Society.

Respecting these remedies, Professor C. Morren (no mean authority on these subjects) states that salt, lime, and bluestone, (sulphate of copper,) strewed over the land, will destroy the disease; but he does not give, or I have not seen, the experiments by which he substantiates this fact. I found

that these remedies destroyed the *mycelium*, and all other propagated parts of the fungus, except the spores; but if they are destructive to the vegetation, where they are found the spores cannot vegetate. My object in recommending the application of salt to the soil, was, that it might be taken up in a liquid state by the roots, and circulate throughout, thus preventing the beginning of the disease, which Professor Morren states to originate with the vegetation of the fungus spores in the leaf. The British professors, in their first report, decry the use of salt to the potato when dug up, as accelerating the progress of the disease; but in their last report they recommend strongly to steep the sets, previous to planting, in a solution of salt and bluestone. The truth as respects the application to potatoes dug is, probably, that if the disease is already under the skin, the salt cannot penetrate, and then, unless the brine were very strong, the moisture of the solution may accelerate the progress; but I do not believe that an entirely untainted potato, if covered with a strong briny solution, will ever receive the disease.

The instances where salt has been used in the soil, and the potatoes have escaped, are not unfrequent; after numerous inquiries, I have heard but one solitary exception; where six bushels to the acre had been *harrowed* in, the potatoes had the rot the same as those without salt.

I admit that this alone would be fatal to the virtue of the remedy, were it not for one circumstance. I found, on inquiry, that the soil was the stiffest and most unyielding clay. Into this water cannot freely penetrate, much less water thickened with salt; the experiment, therefore, does not prove the use of salt, for in every probability it was washed from the surface, or never penetrated to the roots of the potato. I have not the slightest objection to surrender my opinion, when it is found not just.

There are several instances in which the application of chlorine gas has clearly destroyed the disease; but this application is impossible on a large scale, and is, besides, liable to very dangerous and fatal accidents; but salt is a mixture of chlorine and soda.

Unslacked lime will also destroy this fungus, and must therefore be a most excellent addition to the soil with salt; but lime is not so easily caused to circulate in the juices, except as lime water, and then the acids in the plant would quickly saturate it and change its nature; in addition to which, it soon attracts carbonic acid from the atmosphere, and becomes carbonate of lime, in which state its powers on fungi are very questionable.

The most important object is now to provide for the next year's crop—both potatoes to plant and soil in such a state as to offer the fairest hopes of obtaining it free from this dreadful disease; for if it occur the ensuing season with the virulence of the present, we may bid adieu to the potato; nay, for aught we know, it may attack some other vegetable of equal importance.

I have studied and reflected much on the subject; the result is the following recommendation:

Let the potatoes intended to be planted be selected with the greatest care, with the fairest and cleanest skins, rejecting all such as have small, dark, soft pustulous looking spots, which are often not larger than the head of a pin; powder them over very liberally with fresh quick lime, and keep them as warm and as dry as possible; it is indispensable, however, that the warmth be a dry heat.

The spot for planting should be a good loamy virgin soil, or a spot that

has not been broken up for years, and as dry and well drained as can be had. Do not use any manure; put in guano if so minded, as it is not possible that the seed of the fungus can exist in it, whereas manure may be a fertile source of them.

Just before planting, plough both lime and salt into the land, then steep the tubers in a strong solution of brine, to which a little bluestone (sulphate of copper) may be added, and commit them to the soil. I have not said anything respecting quantity; this must depend on the soil.

An addition to the report of the British professors gives a favorable opinion of peat, bog ashes, and the water from peat bogs. I notice this, to warn the farmer that the bogs here do not quite resemble those in Ireland, and, in my opinion, would not be equally efficacious, for reasons which would be too long to detail; but their idea appears to me to be well founded, and worth extensive trial with the English and Irish peat, in which all kinds of vegetable and even animal substances have been found in a perfect state of preservation, although they have lain there imbedded for centuries.

Yours, most respectfully,

J. E. TESCHEMACHER.

Edmund Burke, Esq., *Washington.*

New York, *November* 17, 1845.

Dear Sir: I promised you the result of some experiments which I made on some diseased potatoes, and it is as follows:

I selected a quantity of these roots from a lot which had been rejected as unfit for use. They all were affected. I divided them into three parcels. The first I subjected, for twelve hours, to a weak solution of chloride of lime in water. The second was, in like manner, subjected to the action of a saturated solution of recently burnt lime in water. The third lot was freely sprinkled over with recently burnt lime-water, slacked to dryness.

The two first lots were, after being so treated, placed on a brick pavement under cover, and the third lot was suffered to remain partially covered with dry caustic lime, and all of them so suffered to remain for six weeks; when they were examined, and the disease found to have been wholly arrested.

The potatoes, however, in the first and last lots, had somewhat shrunk, owing probably to the too caustic treatment which they had received; but the second lot, or that which had been steeped twelve hours in lime water, were plump and good; and, when boiled, the diseased portions or blotches came off with the rind. The parcel from which I took the potatoes on which I experimented continued to perish, and were finally thrown away as worthless.

Exposure to the atmosphere in a dry place may have had a beneficial effect; but the disease is, beyond a doubt, occasioned by *fungi* of a very delicate texture, which were destroyed or decomposed by the acrid substances to which they were exposed. If mistaken in the character of the disease, and it should ultimately be found to result from the depredations of animalculæ, the cure may be ascribed to the same cause.

The results of my experiments induce me to believe that the absence of a sufficient quantity of lime-stone (carbonate or phosphate of lime) in soils is the cause of the disease in the potato. If it be owing to other cause or

causes, the remedy indicated, it seems to me, is the free use of lime, water-slacked to dryness, or of unleached ashes at the planting or first dressing season of the potato; and I suggest to farmers, who have suffered from this widespread pestilence in their crops, to try whether a judicious use of these materials may not prove a corrective for, or preventive of, this disease.

With great respect, your friend and obedient servant,

EDWARD CLARK.

Hon. EDMUND BURKE,
Commissioner of Patents.

CALAIS, ME., *January*, 1846.

SIR: The potato disease prevailed the past year in the whole State of Maine, in the Province of New Brunswick, and to some extent in Nova Scotia. In the eastern part of Maine, where there was no disease the year before, it was the most destructive the past year.

I cannot give you its cause, nor a remedy; but will give some incidents relative to its character:

Some of my seed potatoes I cut, and put lime in the hill with them when planted.

Some I planted whole, with lime.

Some cut and some whole ones, without lime.

Some seed I procured from a distance, and which was grown upon a different soil entirely.

In some of my compost manure I used a large quantity of potash.

In all these cases the disease upon the potato was apparently the same; nor did the quantity or quality of the yield vary. The greatest difference was found in potatoes planted upon different soils. On that soil which was stimulated most by manure, (and especially by manure in the hill,) the "rot" was the greatest. On dry loamy soil the disease did not affect the potato so much. On wet land, and especially on wet clay land, the disease was most fatal. It was observed, that where lumps of clay lay so near to the new grown potato as to touch it, the potato would be rotten on that side touched by the clay. The potatoes which grew nearest the surface, and nearest the stalk, were also observed to be most rotten. Those soils on which the salt rock-weed was used as a manure in great abundance, and where the influence of the salt-water fogs was felt, were equally if not worse affected by the disease.

One experiment I made, the result of which I think important. As the potatoes were dug, a part of them were put into barns, and a part were put in heaps of fifty bushels each, on a dry part of the field, and covered, first with straw and then with dirt, four or six inches deep. I left them here as long as it was safe, on account of the frost. We found, in taking those from the barns to the cellar late in the fall, many of them had rotted, and others looked sickly. But those we took from the heaps in the field to the cellar (being the latest removed) were as bright and sound as when dug, except a few which had entirely rotted, and which we supposed had commenced rotting before put into the heap.

I am, sir, respectfully, your obedient servant,

GEO. M. CHASE.

Hon. EDMUND BURKE,
Commissioner of Patents.

ARE THEY ALL MISTAKEN?—POTATO ROT.

To the Editor of the Maine Farmer :

Dear Sir : As one of the many who are particularly interested in the potato malady, I have watched narrowly the thousand and one plausible and *unplausible* conjectures about the cause of the potato disease, so universally prevalent in the potato kingdom of all Up East. I find as great a diversity of opinion upon this subject as there generally is on all others that call forth the expression of the multitude.

The potato rot will seriously affect the *deposites* of thousands in our State ; but let us bear in mind that all the *rottenness* in the body politic is not confined to the potato tribe.

That the potato rot is caused by the drought, or moisture, cold or heat of this or the past year, or that it is caused by cutting the seed, or by an insect wounding the tops, or the premature killing of the potatoes by mildew, rust, or frost, I cannot believe ; and I will give you the reason. Last spring, the thought struck me that potatoes would, if left in a cellar through the summer, produce new potatoes ; and accordingly, to try the experiment, I laid a few (say half a bushel) on some dry tan bark, in a dark dry place in my cellar. Yesterday I took some of them out, and on examining them I find quite a number of new potatoes, from the size of a hen's egg down to a mite, as you will see by the examples I send you ; and on examining the new potatoes, I find among and upon some of them precisely the same appearances of the disease and rot, that I did in diseased and rotten potatoes in the field in its first stages. Of course you will bear in mind that the disease on those I send you must be in its first stage.

Now, Mr. Editor, by this you will see, that if the disease in the potatoes that I send you is the same as that confined to those grown in the open air, it is all folly to talk about rust, the heat, cutting the seed, &c., for none of these, I presume, caused the rot among those grown in my cellar.

My opinion is, that the cause is in the potato, and in the potato alone. It is universally the case with us, that the richer the soil is in which potatoes are grown, the more and faster do they rot when in the ground.

You may hear from me again upon this subject, but my engagements at this time will not allow of more at present.

Truly yours,

E. G. BUXTON.

North Yarmouth Centre, *October* 9, 1845.

Note.—We have examined the potatoes which friend Buxton has sent us, and can see no difference at all in the disease that affects them from the disease in the fields. They can be seen at our office.—Editor.

For the Boston Cultivator.

THE POTATO DISEASE.

Messrs. Editors : Much has been said and written on the rot in potatoes. With your permission, without pretending to solve the question, I will make a few remarks upon the subject, which may or may not cast some light upon the cause and remedy. Perhaps no subject has perplexed and

baffled every one more than this. Some have supposed it to be the electrical influence upon the tops. Others have held it to be something peculiar in the soil.

I am inclined to suppose that the leading cause is in the soil. If so, the remedy must there be sought. From all that I can gather from what I have seen and heard, it appears to me that it is mostly from mismanagement in the husbandry; the air and electricity have probably much to do in the case. As far as I can learn from inquiry, I am satisfied that the potatoes rot most where they come most in contact with manure, especially sea-dressing.

The immediate cause of rot is probably a blight of some kind—rust, or some other—on the tops. This more or less diseases the stalk, root, and tuber. In proportion to the violence of this blight, the rot probably progresses. Manure coming in immediate contact with the growing crop, by being put in the hill or spread upon the ground, forces the growth, especially of tops, too fast. This renders the substance of the tops too loose and too much inclined to fungus matter. Therefore, whenever a sudden change has come, from a hot day to a cold night, and then to a hot sun again, the tops have not had stamina of constitution sufficient to stand and withstand this change. The consequence has been diseased tops, which, in the end, has diseased the whole system. I am disposed also to think that the latent cause is a good deal in not ploughing the land sufficiently deep.

I am apprehensive that manuring on the top of the ground and in the hill induces too much growth in the early part of the season; the roots, which seek moisture, coming in contact with the hard ground below the ploughed stratum, are resisted in their progress, and become unable to supply the plant with sufficient moisture from the earth. In the mean time, the roots which were near the surface to collect the solar influences for the plant, and the leaves of the plant which collect from the atmosphere having their full operation, supply more of their relative proportion of matter toward the general growth, than the descending roots can—an overstock comes to the plant, and produces disease.

The natural inquiry here comes, what can be the remedy? I candidly confess I do not know; but I will suggest my opinion. I am inclined to think that potatoes would do better, all things considered, without any manure in the land. But should manure be applied, let it be ploughed in to the depth of 15 or 16 inches—more if possible. The depth of earth would be sufficient for the descending roots to gather moisture through the season, to act in concert with other roots and the leaves, thereby preserving a healthy state of the plant. This disease, whatever it is, comes from an over-action in some part of the plant, and a minor action in some other part. And it is very evident that the roots cannot penetrate the hard unbroken ground below the ploughed stratum, to obtain moisture. It is very evident, too, that no plant can grow and be healthy when deprived of proper moisture.

I would also suggest one other thing concerning the cultivation of potatoes—the planting in drills. After ploughing the land as deep as possible, just make a mark (not a furrow) for the rows; then, after dropping the seed, turn back furrows upon the seed, putting on all the earth that the future crop will require. Afterwards, to subdue the weeds, run a light fine harrow over the gound, as often as necessary. Then the crop will all set at once, and all will be sizeable; having no small, worthless potatoes. It is well

known that by adding earth about the tops of potatoes sets a new crop every time that the addition is made. It is also well known, I believe, that these successive crops are of very little, if any, value to the owner.

My notion about the growth of vegetables from the three causes—the united effects of the watery roots, the solar roots, and the leaves—may or may not be novel to others; but I am strongly persuaded that these three are the main causes of growth, health, and disease in all vegetables. Other causes undoubtedly operate, to wit: the electrical; but these are so subtle and fine, that we cannot go much into a definition of them. We can do but little more than talk about them; but whatever agency and effect electricity may have—and it is undoubtedly very great—I am inclined to suppose that that agency depends very much upon the due and proper management of the three causes which I have noticed above.

I will say one word more upon the subject, and close. So far as I can learn, the long red potato does not rot so bad as the other kinds. If this is true, that variety should be sought and planted the next season, in preference to any other. It is also undoubtedly the richest and most productive of any kind that we have. The potato crop is now almost the standard of life on the face of the earth, and no labor, research, nor investigation should be spared to prevent it, and protect it from loss. So far as we know now, we have no substitute for it.

PHILO.

PORTLAND, *October*, 1845.

THE POTATO DISEASE.

To the Editor of the Bangor Whig and Courier:

With your permission, I propose to review some of the opinions put forth and entertained on the subject of the death and rot of the potato.

And, first, of disease. Very learned professors have asserted, and continue to repeat, that the potato is diseased—dying out; and most persons believe it; and the question is often asked, what shall be substituted for the potato? The sudden death of the potato top, and the subsequent rotting of the tubers, are said to result from disease in the seed planted. But what are the facts offered to demonstrate the soundness of this theory? Simply that the tops die, and the tubers rot. And what does this prove? Nothing. On the other hand, the potato tops the present season were seldom if ever more thrifty, or gave greater promise of an abundant yield. Up to the hour of their death, the potato tops of every variety, to all appearance, were never more healthy or vigorous. If this fact affords any evidence of decay in the plant, the advocates of disease may have all the benefit to be derived from it.

It is said by others that the potato top is killed by a worm eating into the stalk near the ground, and making his abode there. This is true every year to a greater or less extent; but the effect is, not to rust or rot the stalk, but it merely dries up, as it would do if cut off. Plants killed by the potato worm emit no unpleasant smell; and, therefore, the rust of the present season is not caused by a worm.

Others, again, assert that it is a little black bug that has killed the potato tops. I have examined a number of fields with particular reference to this

bug. This bug is about the size, skips as nimbly, and will jump as many times his length, as a flea; and, as near as I am able to estimate, would number about as many to a hill of potatoes as there are fleas in a well instructed family of flea catchers. So much for the "little black bug." Now to the remedy. Doctor Jackson says: "I learn that where lime has been used in the proportion of about a table spoonful to a hill, there no disease has appeared." In the same paper he asserts: "No peculiarities of soil or of manures appear to afford any explanation, for the plant appears to have been affected in one as much as the other." This last is true. But how is the common farmer to be instructed by the above statements? Dr. Jackson is a strong advocate for the use of lime as a manure; and, by putting about a table-spoonful in a hill, does the lime cease to act as a manure, and operate as medicine to a diseased plant?

Again, he says, "that after vines had become affected, the best remedy was to cut the stems off close to the ground." This was intended, doubtless, for the instruction of farmers; but before adopting it, I would inquire if it is based upon scientific principles? If we would kill bushes, root and branch, science has told us to cut the stems off close to the ground, in August. Thistles and weeds are killed by the same process. The roots of thistles and bushes are killed more certainly in August than in any other month, because the hot weather of that month is more sure to produce fermentation, or, in other words, to rot the roots. But Dr. Jackson says that when the vines of the potato become "affected"—that is, dead—the best remedy to keep it alive, to prevent the tubers rotting, is to cut its head off!

He says, again: "I observed that the potato began to rot next to the skin, and the disease penetrated inward in many cases to the depth of half an inch." This description is true, and applies to Maine as well as New York, and proves to my mind that the potato had no internal disease, but was made to rot by an external influence. This external influence was fermentation. But the potatoes, it is said, rotted principally after they were dug and in the cellar. Very true; and what was the cause? The month of August was extremely dry and warm in New York, and the month of September in Maine; and although the vines were killed some time before digging, there was not moisture enough in the tuber, or in the soil, to produce fermentation. The fermentation being partial or incomplete, produced a dry rot. When put in the cellar in large piles, moisture collected and caused rot. This has been a wet season, and the rot is not altogether external, or dry. The doctors would call this difference in the rot, I presume, a new type of the old disease.

A Glenburn Farmer.

From the Boston Cultivator.

DRYING POTATOES.

"A Glenburn Farmer" says, in a letter to the editor of the Bangor Courier, "*keep potatoes dry, and they will not rot.*" We copy the following extract from his letter:

"I assume it to be a fact that the potato is not diseased. The tops of the potato have been killed, extensively, the two past seasons, and, as a very natural consequence, the unripe, half-grown tubers have rotted. The cause of the rot is fermentation. Prevent fermentation, and the frightful 'potato

plague' is cured. This must be done by drying. Any farmer who has a rotting field of potatoes may save them by digging and *spreading them so thin as to dry the surface, and keep them dry until cold weather*, and he can then safely stow them away in the cellar. Drying any substance, as every one should know, will prevent fermentation. Fermentation in vegetable matter produces decomposition, and decomposition is rot."

Remarks by the editor of the Boston Cultivator.—Drying potatoes may be a good method to save them from rot, and it may be well to save them in this way; yet by exposure to the air they will lose much of their good quality. If potatoes lay in a box or barrel, open to the air, and in a room, shed, or other place out of the cellar, they will lose much of their good qualities in five or six weeks. To preserve potatoes in good condition, they should be dug with as little exposure to the air as possible, and put in a cellar, in a close bin, cask, or box, and the cellar should be closed so as to exclude light and air. Yet it may be better to save them with a loss of a part of their good properties, than to let them decay; but we would caution the lovers of good potatoes against too much exposure, as it will cause a great depreciation in their value.

From the Ohio Cultivator.

A FEW FACTS ABOUT POTATOES.

Mr. John M.c Guffy, of Truro, in this county, (Franklin,) informs us that he planted, on the 28th of May last, two patches of potatoes, of about one-sixth to one-fourth of an acre each. One of them was on land on which cattle were fed (fattened) with corn the fall previous, by which means it was highly manured. On this land one bushel of seed was planted, of the Mershannock variety, cut into small pieces, and three or four pieces dropped in a hill; the hills four feet apart, and the ground well cultivated during summer. The tops grew with great vigor, covering the whole ground; and owing to the fine rains of the latter part of summer, they continued to grow until destroyed by frost in autumn. On digging, the product was found to be $77\frac{1}{2}$ bushels, (from the one bushel of seed,) and the appearance of the potatoes was very fine.

The other piece of land, of somewhat less extent, was planted with three pecks of the same kind of seed, but *no manure* had been applied, and less labor was bestowed in cultivation. The weeds were allowed to grow after wheat harvest, and the tops, which were much less luxuriant than of the other piece, were all ripe and dead before frosts came. The yield of this patch was only $24\frac{1}{2}$ bushels.

Both these lots of potatoes were dug at the same time, and buried in the same manner, in trenches in the ground. In a few weeks it was discovered that those from the rich ground, and which had the tops destroyed by frost, were beginning to rot. They were soon taken out of the trenches, sorted and dried, but the disease continues to spread among them to such an extent that it is doubtful whether any will be saved. But those from the ground which had no manure, and where the tops ripened before the appearance of frost, have not shown any symptoms of decay.

Mr. Thompson, on a neighboring farm, also had a patch of potatoes

which were ripe before the frosts appeared, and his have shown no disposition to rot; while another neighbor, Mr. Miller, had a patch that was green until killed by the frost, and his potatoes have nearly all rotted.

These facts have induced the farmers in that township to suppose that the disease is caused by the killing of the tops before they were done growing. This, we believe, has in many cases appeared to *induce* the disease, but many facts have been found to prove that it is not generally, if ever, the ultimate *cause* of the evil.

From the Boston Cultivator.

CAUSE OF THE POTATO ROT.

E. G. Buxton, in the Maine Farmer, states an experiment which he made in growing some potatoes in the cellar, in a dark place, and they were affected with rot, like those raised in the field. From this he infers that the disease is not caused by rust, heat, cutting the seed, &c., but that the cause is in the potato. Some person, commenting on this, attributes the cause to disease in the previous crop, which was not perceptible, and was transmitted to the new produce.

We do not believe in either of these causes. We do not think the potato is running out, or generally declining, and will finally become extinct, as is said to be the case with some species of animals and vegetables; which is the view, as we suppose, that Mr. Buxton takes of the subject. And though the disease may in some cases be transmitted by planting infected seed, this is not the general cause; for, on this principle, how did it originate, and why does it prevail to a vast extent this year where it was unknown before?

Then, what is the cause? is a question that will naturally be suggested in the minds of our readers. We expressed our opinion when this subject was first agitated, and the hundreds of causes assigned, and the numerous arguments offered in favor of one supposed cause and another have only tended to confirm us in our opinion, which is, that the disease is caused by an *unfavorable atmospheric* influence. This is rather indefinite, but we would rather be *indefinitely correct* than *definitely wrong*.

Now, as no cellar is air-tight, and probably no cellar is kept shut during the whole year, the same air that generally prevails around a cellar must in some measure pervade it. Our object now is not to defend the position we have taken; we have before given some reasons for it, and we may give more at another time, but we wish to show that the causes above assigned are not correct, and that the case named does not in the least militate against the view which we have taken, and frequently expressed.

For the Indiana Farmer and Gardener.

THE POTATO BLIGHT.

Mr. Editor: Something like ten days ago, and after the late rains had commenced, I discovered that the leaves on the tops (of one patch) of my potatoes, which extended horizontally, were dead. They had the appearance

of having been frost-bitten, and were of a dark brown color. I attributed it to too much wet, as they were situated in a low piece of ground, where the water (when it falls as copiously as it has of late) stands for some time after falling. I took no further notice of it till two days after, when I found the entire tops were in "the same fix," though they always had kept their erect position. It occurred to me then that the disease so much spoken of in the east had extended to this region. What are the symptoms of that disease? Does it show itself this early in the season? I have examined another lot growing on high ground, which is yet entirely free from this defect. I send you by the bearer a sample of the affected potato tops, that you may examine them for yourself, and give your numerous readers your opinion upon the subject. Yours, &c. M.

For the Genesee Farmer.

THE POTATO DISEASE.

Dr. Lee—*Dear Sir:* The writer of an article copied into your December number says: "Be very careful not to plant potatoes infected with the disease. Avoid planting potatoes in places where they grew this year." The following facts illustrate the respective value of these two directions. Upon a farm I have in Bradford county, Pa., there grew in 1844 three fields of potatoes. They were planted before I came into possession; but I believe the seed was all sound, and from the same stock. One field was new land, very high and dry. The other two were older land, lower and moister. Every potato grown in the first field was sound. In the others some were diseased. The next season, (1845,) one of the lower fields was again planted, using seed from the high ground. The summer was drier than in 1844, and the produce was all sound; as was also that on some adjacent green-sward planted with the same seed. Further to prosecute the experiment, I had some infected seed planted on a part of the green sward, and there the crop was more than half lost. There was no communication of the disease, though the sound and diseased hills were but three feet apart.

In my professional rides over the mountains and valleys of Bradford and Chemung counties, I have observed the farmers in the valleys suffering so much the more from this scourge, that I have often advised them to procure seed from their highland neighbors.

The inferences from my observations are, that the disease is not contagious; that it is perpetuated by infected seed, and not through contamination of the soil; and that low, moist localities are most obnoxious to its influence.

SUMNER RHOADES, M. D.

Blossom's Hotel, *Rochester, December*, 1845.

For the Boston Cultivator.

THE POTATO DISEASE.

Messrs. Editors: For some years past a great deal has been written on farming, and I have read much on the subject, and I think it has been a

great benefit to me. I find much in your paper on the potato rot, and I will add a fact from my own experience. My potatoes first rotted in 1844, though not so much as my neighbors. I dug and put them in the cellar as usual, where they rotted badly.

This year I planted in several places, and some of them were badly cracked and very poor, but on one piece a part of the land descended to the north, where the influence of the sun was less, and on this part I had as good potatoes as I ever raised. For twenty-five years past, the potato crop has generally succeeded well among us, and I intend to continue to improve the seed time, expecting to gather a good crop.

EDMUND L. LANE.

KILLINGWORTH, CT.

From the Worcester Spy.

One of our subscribers informs us of a fact, which may be of some practical importance, in relation to the rot in potatoes. He says that he raised in his garden, the last season, six or eight bushels of the "Schaghticoke," or peach-blow potatoes. A part of them were carried directly to the cellar, and put in a barrel; the remainder were put upon the wood-house floor, where they remained two or three days, till they were well dried, after which they were put into the cellar. Those which were first put into the cellar, in a barrel, decayed entirely, while the others remained sound through the winter, and were good potatoes for cooking. If a short airing and drying, after potatoes are dug, will have the effect which it appears to have had in this instance, it is a very important fact, and ought to be generally known.

From the Ohio Cultivator.

THE POTATO ROT.

The editor of the Sandusky County Democrat says: "We hear almost a general complaint, among the farmers of this county, of the potato crop being affected with the *rot*. The crop has turned out better than any one expected three months ago; but since it has been gathered, and the existence of the disease known, doubts are expressed as to there being enough for home consumption for the year to come. Some attribute the rot to the drought; others, to a particular soil. We should like to have the opinion of the editor of the Cultivator, or any of our experienced farmers, upon this subject."

From the Boston Cultivator.

It seems that the prevalent disease has not long existed in the potatoes; that there has been a gradual increase; which demonstrates it to be something more than mere casual. But I notice several combined causes which promote this rot in the potato, which I think can be obviated in a great measure In the first place, we know the potato is a tender plant, and cannot withstand a great deal of hardship; we know, too, that the past season

has been one of great extremes of heat, dryness, and moisture—consequently unpropitious for the potatoes. I speak particularly of our vicinity, where the earth was so severely parched, wet, and dry, that we had nearly given up all hopes of a crop. After a very heavy rain it remained hot, while we had alternate extremes of heat and rain, which set the earth in a great fermentation, a state very injurious to some sorts of vegetation. From notices I have taken the present and last season, it appears to have had great effect, and almost exclusively on rich moist soils, or moist soils highly manured. In my observations and inquiries I have found a failure of more or less by rot, and often a total loss. Our crops commonly are 500 to 2,000 bushels. I have heard of instances of good crops from new sward, without manure, but in this mode there are failures. I have taken some pains to go on different fields to ascertain facts, and nowhere have I found any rot on light soils lightly manured. I can give no better account of a successful culture than to name my own of last year—1844.

We planted pink-eyed potatoes—some early, on high ground—manure spread. We ploughed in June a piece of rich clay loam, manured in the hill, (a common quantity,) and planted the same kind. They yielded well. We harvested about 400 bushels; put them in the cellar without any suspicion of rot, but soon found, by close examination, that they were decaying. The whole were overhauled in season, and were nearly all saved. I planted a small patch of long reds on very rich moist soil—found them considerably rotten.

From these circumstances, and looking a little farther among my neighbors, I this year was so wary as to plant all light ground, some sward and some old ground—all planted early—all manured in the hill lightly with compost manure, made from rich low ground, hauled into the yard after haying, to mix with cattle manure, and hauled out in the fall. This kind of manure will not ferment. My crop this year is tolerably good, and all sound. I will observe, that I planted several pieces and many varieties of potatoes. It is found that the early planted better escape the rot than the late.

From what I have seen and heard, I may presume to say, that if we have just such another season as the last,(which was a very uncommon one,) by pursuing my practice, with my advice, farmers may raise a crop of good potatoes, although not so abundant as usual on rich soil. There is a diversity of opinion as to the cause of this rot, and its various operations. It is certainly new; and I fear it will continue, in some degree, in more temperate seasons than the last. We have, however, great reason to expect more congenial seasons for the potato crop; less extremes; light and frequent rains—never so heavy as to wet through all the hill, especially after the potato is half grown. They will not live long in a quagmire, or in earth full of water. The rust and specks in the stalks, and falling of leaves, all proceed from the affected roots. Reduce either of the causes named, that combine to effect this rot, to a medium, and the rot will not be produced. For instance, plant rich moist ground, the temperature low, and, and with the other extremes, there is no rot; light, even rains, with other extremes, no rot. Yet all these causes combined will surely effect a rot; that is, while in a certain stage of growth—not, as some have it, in one certain day or hour. But to escape all these evils combined, plant light ground, manured as I have observed, or without any. Light soils are so porous that they do not retain the abundance of wet; nor is there to

be found the other materials, richness, &c., to co-operate to produce this disease.

Numerous causes assigned for this rot seem to be without proper grounds. Some suppose it to be the effects of electricity. I know not why vegetables should be affected any more now than heretofore, by that component of the atmosphere, which has always existed, and is always necessary, and is no more abundant than usual. Some impute the cause to the "old, long, worn-out" potato as gone down; others to defects in the tops, from rust, and specks of rust—the tops sickening and the disease passing down to the tuber; others, to atmospheric disorders, &c. Are these correct, when, in the same field, side by side, the rich highly manured soils are the only soils where the disease is found, and when on light soils they never have been found with this new peculiar disease? Are not the tops as much exposed on light soils as elsewhere?

A. ROBINSON.

From the Northampton Gazette.

The *potato disease* is noticed in many places. We have seen it stated that those localities which were visited last year have escaped this. This may be true to a certain extent; but that the disease has appeared of a more or less aggravated character in the same localities both years, is unquestionable. The St. Albans (Vermont) Messenger states that the rot is quite extensive in that vicinity. Many fields do not yield as much as the seed planted, and all fields are more or less affected. The disease prevailed to some extent there last year.

We had supposed that potatoes in this vicinity were quite free from the rot; but we learn that many of them are rotting since they were harvested. We are informed that a farmer in Ashfield barrelled and sent to Boston 600 bushels. Soon after their arrival he received a letter requesting him to come and remove his *rotten* potatoes. He immediately went to Boston, picked them over, and out of the 600 bushels obtained only *one hundred* bushels of sound potatoes! The same informant states that many potatoes are rotting in the cellars at Whately.

From the Maine Farmer.

EXTENT OF THE RUST IN POTATOES.

The disease which infests the potatoes, we hear, is very prevalent in the eastern sections of the State, especially in the vicinity of Eastport, and it also extends into the province of New Brunswick. We have not heard from Nova Scotia. It is a great calamity not only to us, but to the citizens of other States, who have been in the habit of depending on Maine for their supply of this useful and necessary article of food. What the real extent of the disease is, cannot be told until the digging season is over. People who dig their potatoes should be careful where and how they put them away, for they will need watching and overhauling, lest a few decayed ones may ruin the whole. We have seen potatoes, that were very fair when dug, commence rotting in a few days, and soon become worthless.

For the Boston Cultivator.

POTATO ROT.

Messrs. Editors: Much has been said and written with regard to the failure of the potato crop, and yet there is much diversity of opinion with respect to the true causes. My theory is, that the potato rot cannot be traced to any single cause, but to a combination of causes, all operating to produce a failure; all of which may be termed atmospheric influences. The failure last year was comparatively slight, and was caused by the potatoes being absolutely baked by the hot days and nights of September. The failure this year may be attributed to other extremes.

From the latter part of May until the 7th of July, the season was very cold, dry, and backward, accompanied with high winds, which seriously retarded the growth of the plants, if it could be said they grew at all. Warm rains then set in, with an extremely high temperature, the thermometer ranging, through July and August, from 80 to 90 degrees. This forced the plants to a rapidity of growth never before known, especially on rich soils, *where the potato has been most affected by rot.* The tender plants, thus quickened into a premature existence, by almost the growth of a day, soon yielded to the influences of the intense heat of the sun, with constant exhalations from the saturated earth. Fermentation followed as a consequence to the tops, and the tubers fell victims as a matter of course. At the time of this process a strong effluvia arose from the potato fields, and it was only necessary to pass to the leeward of them to be convinced of the work of destruction by a sense of the olfactories. Now, as concurring proof, as I have remarked, the potato has suffered most on rich soils—and why? because the tops were more forced in their growth—were more delicate in their fibre—were more susceptible, and more easily affected by atmospheric action.

That we have been visited by unusual atmospheric influences, and that the whole vegetable kingdom has been powerfully affected, is further evident from the sickly hue of the larch, and all the evergreens; in fact most of our forest trees commenced shedding their leafy tributes without the usual aid of frosts, giving token that they were obeying some new law of atmospheric phenomena. Extremes under different phases, or unlike the foregoing, may have produced the same effect upon the potato in other parts of the world. That they have had an extraordinary season in Europe, all accounts agree. It is therefore that I consider the failure of the potato crop in Maine, partially in '44 and almost wholly in '45, as *caused by extremes of atmospheric action*, such as have never visited us before, and probably never will again.

I would take this occasion to caution all brother farmers (and there are many) who have imputed the rot to a disease of the potato, (which will probably continue,) and have determined to plant less, to entertain no such impressions, but to plant the next season with as much confidence as they would, had we never been visited by the calamity. Many have supposed the rot was caused by insects attacking the tops; but, wherever they have been noticed, they have appeared more as a consequence than a cause, for it is well known that all vegetable matter in a state of decomposition attracts insects, or animalculæ.

Yours, respectfully,

HENRY BUTMAN.

Dixmont, Me., *November* 3, 1845.

From the Delhi (Delaware county) Gazette.

Look to your potatoes.—We hear from different sections complaint of the rot in potato heaps and in cellars where large quantities are together. One farmer in Meredith informed us that he had lost about one-half of a heap he had buried. We had a quantity in our cellar examined, and some three or four bushels of injured ones picked out of about sixty or seventy bushels.

From the New York Farmer.

IN THE NEW YORK FARMERS' CLUB.

Chairman.—By treating diseased potatoes with lime, I have observed that the disease was arrested, and when they were boiled the diseased parts readily separated from the sound parts. I believe it to be contagious—not attributable to climate or to season, but to a temporary evil, analogous to that which has affected the sycamore trees.

Townsend, of Astoria.—I have raised potatoes for this market for fifteen years past, and I believe that this disease is owing to the seasons. I have tried all manner of ways with them. Last year they were generally diseased, but this year they are perfect. I planted some and did not till them, to see what that would do; a small crop from that experiment. Those that I tilled with the greatest care were the best. Mine have no disease this year in any way or shape. I generally bring to this market from three to five thousand bushels of potatoes per annum. This year my early ones were a good crop; but my late ones, owing to severe drought, a small crop—but all good and sound. I have spent, in experiments, more than my potatoes this year are worth.

Judge Van Wyck.—Climate and season no doubt aggravate the disease. I found it existing three years ago on my farm in Jersey, in a wet season; and next season, which was dry, worse still. This last season, which was very dry, the rot was worse yet.

Townsend.—I planted from the diseased crop of last year, yet I have good potatoes this season; and I have been offered a dollar a bushel for those of my early crop, but have no more to spare.

Dr. Field.—Last year my early crop was good, and the late were diseased. They were all of the Mercer kind. This year my late crop is good. I think, with Mr. Bridgeman, that those planted quite early or quite late are good—having avoided our great midsummer heat. The red merino potato (a long one) I found best for planting. The disease is fungus, I have no doubt.

Mr. Meigs remarked that many persons uttered impatient observations relative to this hitherto fruitless investigation, but he trusted there would be no relaxation in one so important; that, by assiduous inquiry, mere accident might reveal the causes which no theory could unravel.

Mr. Fleet.—I must say that, notwithstanding all that has been said about the potato rot, hardly a single fact has been made known, which can govern us for the future.

Mr. Hancock.—The soil of Kilkenny is remarkable for the presence of anthracite coal, while that of Athlone is a level peat bog.

Chairman.—The disease is fungus, beyond all doubt.

Mr. Lodge.—There are many species of the fungus. Decomposed vege-

tables produce fungus. I can produce it in that way in a few hours. But a thoroughly clean cultivated potato will have no fungus upon it.

Dr. Field.—It is fungus, which is as perfect a plant as others, yielding its seeds for future growth. When the seeds of fungus fall on the bark of healthy trees, they take root and grow.

* * * * * * * * *

Col. Clark.—I reiterate the experiments which I have tried on the disease. The first was by a weak solution of the chloride of lime. 2d. A saturated solution of the same. 3d. Pure quick lime. Potatoes in the first shrunk; in the third, shrunk considerably; and in the second remained plump. These potatoes, when boiled, were good; all the diseased specks, from the size of a pea to that of my thumb-nail, came out of the potato, leaving the rest good. The disease is undoubtedly fungus, and the saturated solution No. 2 destroyed it. With a powerful microscope I did not discover any insects. The want of an adequate portion of lime in soil, may, in a measure, account for the existence of this disease. Recent quick-lime or unslacked ashes applied, will, I think, cure the disease.

Mr. Wakeman.—The London Farmers' Magazine for last October states that salt and lime are deemed capable of preventing or curing the potato disease.

Mr. Steele, of Jersey City.—I laid in my winter stock of potatoes, and lately found some rotting, (melting, as it were ;) the liquor, touching sound ones, caused them to rot. I have separated them. I think the disease is fungus.

Col. Clark.—The causticity of the lime destroys the fungus: potatoes should be kept dry.

FARMERS' CLUB—LIME FOR POTATO ROT.

To the Editor of the Farmer and Mechanic:

SIR: In your paper of the 20th November, 1845, under the caption of "American Institute—Farmers' Club," I have been reported to have said, in respect to some experiment which I had made, corrective of the disease in the potato, which is in a greater or less degree prevalent throughout the civilized world, that the first application to the potato "was a weak solution of the chloride of lime; 2d. A saturated solution of the same; 3d. Pure quick lime." This representation is incorrect, and calculated to mislead and produce injury, inasmuch as the adoption of such treatment in detail, as set forth in the report, would be productive of real mischief—at least, so far as a saturated solution of the chloride of lime is concerned.

In the remark which I made at the Club, I stated that I had made three experiments, curative of the disease in the potato.

The first consisted in subjecting them, in their diseased condition, to a weak solution of chloride of lime in water for twelve hours.

The second, in steeping them in a saturated solution of common lime-water, made by putting a lump of recently burnt lime in water, for the same length of time.

And the third consisted in sprinkling the potatoes, in their moist state as taken from a heap, with recently burnt lime-water, slacked to dryness.

The potatoes treated in all these modes were kept under cover, and spread so as to dry; and the disease which had attacked them was wholly arrested, (insomuch that, on being boiled, the blotches or affected parts came off with the skins,) while those which were neglected, and from which those experimented on had been taken, continued to decay, and were finally thrown away.

The potato treated with a weak solution of the chloride of lime had shrunk considerably, as had those also which had been sprinkled with dry quick-lime; but those which had been steeped in common lime-water were plump and in good order for cooking. From all which it follows: First, that the potatoes steeped for twelve hours in a saturated solution of recently burnt or quick-lime in water, and then dried, were the best. Second. That the other two were shrivelled—those sprinkled with dry quick lime the most so; but both, after an exposure to the air about six weeks, were edible.

From these experiments, I have reason to believe that the disease in the potato may be prevented by a slight application of finely powdered quick-lime, or of unleached ashes, at the planting or first dressing season; and I recommend to farmers to make trial of this simple and economical preventive.

Yours, respectfully,

EDWARD CLARK.

NOVEMBER 29, 1845.

From the New England Farmer.

FIRST AGRICULTURAL MEETING AT THE STATE HOUSE, BOSTON.

Hon. Mr. Stone, from Hardwick, made some remarks on the subject of rot in potatoes. He said the lady-finger kind had not been injured. The long red had also escaped the contagion as generally as any kind. He hoped that more people would communicate facts on this subject, to enable us to come to some general conclusion as to the cause of rot.

Mr. S. W. Cole said he passed through towns in Maine last fall, and he found the lady finger had been affected as much as any kind. He found that the long red had escaped as free as any species that he had seen. He made some remarks on the remedies that had been recommended. Salt had been used in various ways, but he thought salt had done no good; for potatoes near the sea-shore, and potatoes covered with sea-weed, were found as much affected as any others.

Mr. Cole thought the rot should be ascribed chiefly to atmospheric influence. He said apples of various kinds had been affected in the same way. Jewett's fine red he had known for thirty years, and he had never seen it so much affected with rot as in the last autumn. He thought the atmosphere might affect various kinds of fruits in the same way as it affects the potato.

J. A. Morton, esq., from Hadley, said he could not learn much from any one as to the cause of the rot. Where he put lime in the hill last spring, his own potatoes were not rotten: he put a small handful in each hill.

From the N. Y. Farmer and Mechanic.

Morrisania, *December* 16, 1845.

Dear Sir: I have paid some attention to the many complaints that have gone the rounds of the papers relating to the disease in the potato. And truly it may be so called, as, in all instances where lands are not tilled properly to carry out the work natures requires, disease will more or less follow; and here I beg leave to remark that ever since the *solanum tuberosum* was introduced into Europe, which is now only two hundred and forty-eight years, it has been improving in quantity and quality, and is invariably best where most labor has been bestowed upon the land. Our seasons vary—sometimes very hot and dry, followed by heavy freshets and floods. Lands thus drenched, and not drained by proper deepening and breaking through the hard pan, must suffer, and will inevitably cause curl in the leaf, premature its growth, and stop the progress of the tuber, and in this tender state disease will follow. Some persons will say, " my land lies high and dry," and therefore does not require draining, but moisture. Then I say, deepen your land, that it may receive rain when it comes; and by continually working the crop you will retain it. This vegetable should be kept in constant growth until it is matured, or the crop will fall short. To do this work properly, turn your potato land in the fall; again as early in spring as possible; cross-plough with the sub-soil, or trench. Manure broadcast—compost is best—charcoal, animal and street manure, ashes, sea-sand, lime, soot, &c.; add to this as much vegetable and barn-yard manure, and put fifty ox-cart loads to the acre, and well attend your crops while growing, and you may expect to receive a full reward and no disease. Some will say, " my land is worn out;" this is ofttimes a fact. Then, again, I say, till and dress; for when the lands have been longest under cultivation, and most labor bestowed, with good judgment, there is best potatoes and best crops. If our laborers are high, and cannot work quite so close as in Europe, we can take the broad field culture and the advantage of two hundred and forty eight years' of experience, and, with one or two yoke of cattle and sub-soil plough, equal any of our wishes.

I will refer our farmers to last summer's dry weather, where lands were not tilled. It was as dry as though rain had not been upon it for years; and when the plough was kept constantly at work, the moisture was retained, the lungs, fibres, and tubers fed, and a full crop obtained; and here I do not wish to leave you, for all esculents and roots naturally require their soils tilled deep, to allow the frost, sun, wind, air, and all other natural elements, with summer and winter fallowing, to cause a wholesome, good, and full crop; and by strict adherence to labor and nature, you may raise any quantity a reasonable man may desire. And as crops of the above are invaluable for all farming purposes, particularly in wintering cattle, as you will bring them out in the spring to fill the pail, or bring down the scale, your yard will be filled with manure, ready for any crops you may apply it to. Yours, &c.,

J. LODGE.

P. B. Wakeman, Esq.

Mr. Lodge presented to the club ready boiled a dish of his last crop of potatoes, which were eaten by the members, and found to be fine and mealy—excellent.

A letter was read from R. L. Colt, esq., of Paterson. Extract: "Let me tell you about my experience with potatoes. The crop on my grounds is short, but free of rot. I have cultivated old grounds, and used on them a compost of one part salt, one lime, one plaster, and two of wood ashes. Also, the same with guano mixed, and the same with bone dust mixed. There was very little difference in the result—rather in favor of bone-dust and guano. On new ground I used ashes, salt, and plaster; on this I had the *best* potatoes, but no rot in either. From this, I came to the (perhaps wrong) conclusion, that salt, lime, and plaster of Paris will prevent the rot. At all events, I mean to try the same experiment next year, and not put barn-yard manure either to corn or potatoes. My barn-yard manure I put in a heap, mix it with lime, ashes, and plaster, and, when well rotten, and all seeds destroyed, put it on the grounds."

From the New York Farmer and Mechanic.

FARMERS' CLUB.

POTATOES.

Nathaniel Sands, Esq., of New Windsor, Orange county.—I will state my experiments in raising potatoes. I have found that in planting them as early as possible I have good crops. The tops perished in August. I let the potatoes lie in their hills till September, and had perfectly sound ones. I have seen some disposed to decay, upon which I put lime, and these were saved from further rot. A neighbor of mine had a pond, from which he let the water flow upon his potato field in dry weather. For ten years past he has had always sound potatoes. They are of a fine quality. To prove the efficacy of this watering of his potatoes, he had another field which was left dry, and there his potatoes rotted. There are many fields which may be selected for potato planting, so situated as to admit of such watering.

Mr. Wakeman.—From the examination which I have made of this subject, early planting cannot be altogether relied upon. Some late planted crops were good, while the early ones were rotted. A good crop seems to demand all the benefits of a favorable season.

Mr. Chapin.—I have examined the proceedings of the Entomological Society, and will present at the next meeting of this club their conclusions relative to the insect theory as affecting the potato.

Mr. Wakeman.—The opinion that the potato disease is owing to the length of time which the potato has been domesticated, seems to be the better one. The potatoes which we now have are all descended from those first carried to England by Sir Walter Raleigh.

Mr. Sands.—In 1843 I first noticed this disease. I took pains to procure tubers from sound crops. I planted them very early; they grew well and kept sound. Those which I planted in April were good. Those I planted on the 25th of May proved nearly all diseased. By my mode, we seldom now have a diseased potato; and, generally speaking, those planted late proved to be good.

I suppose that our bad seasons for potatoes have been those of great drought, followed by heavy rains.

Mr. Wakeman.—Doubtless a regular supply of moisture will insure a healthy product.

Mr. Sands.—The tops of my potatoes totally died in August, but the potatoes kept well in their hills till dug in September. What I call late planting is late in June. I do not let my planted potatoes be in immediate contact with the manure in the hills. I find that when the rain comes, and soaks through the soil and manure, the potatoes do better than when in close contact with the manure.

JANUARY 20, 1846.

From the Albany Cultivator of December.

POTATO ROT.

In this section we have heard but little complaint in reference to the disease or rot in the potato, this year, till since the crop was harvested. In some other neighborhoods, too, we have heard that heavy losses have been sustained by the potatoes having rotted since they were dug, though while the crop was growing it exhibited generally a healthy appearance. The Boston papers make complaints of potatoes rotting much in the cellars; and within a few days we have heard of many having rotted in this vicinity. Some kinds seem to have suffered more than others; the very excellent kind called *Carters* appear, from statements we have heard, to be more inclined to rot than others. A gentleman in this vicinity, who raised this kind quite largely, has lost half his crop since they were put in the cellar. The Shakers, located at Watervliet, also raise the Carters largely. They informed us a few days since that they had lost from $600 to $1,000 worth of this kind since they were dug. As to preventives, it is agreed that they should be carefully sorted over, rejecting all that show the least unsoundness, as soon as they are discovered to be rotting. The Shakers inform us that the best remedy which they have discovered, (and they have tried many,) is to *dry them thoroughly* by spreading them exposed to the air. This, they say, will stop the progress of decay, and it is the only way they know by which it can be stopped.

From the Ohio Cultivator.

USE OF SALT AND LIME.

The Akron (Ohio) Democrat states that the Rev. Mr. White, of that place, in removing some potatoes, filled two barrels, one of which had been used for flour, and the other for salt, from the same heap, and put them side by side, covered with the same boards. After some time, those in the salt barrel were found perfectly sound, while those in the flour barrel were all, or nearly all, rotten.

This would go to prove, what has before been asserted—that *salt* is, in some cases at least, beneficial in preserving potatoes from the rot after harvesting. *Lime*, also, has been found useful for this purpose; but more experiments are needed with both, before the question of their utility can be fully settled.

From the Albany Cultivator.

THE POTATO ROT.

Mr. Editor: Although a farmer on rather a limited scale, it has fallen to my lot to make a few observations relative to the disease called the rot in potatoes, which, were they published, I have thought might be of service to some of the agricultural community.

In 1844, I planted potatoes on three different parts of the farm on which I am situated. From part of one small field, consisting chiefly of a loose gravelly soil, I obtained about eighty bushels of potatoes; and among these eighty bushels there were probably near a peck of rotten ones, and almost all of these grew on a part of the field which was lower than the rest of it, and where the soil consists, to a considerable extent, of loam and clay. The field I have been describing was ploughed twice before planting; and in that, as well as in the subsequent work among the potatoes, it was my aim to work when the land was in a sufficiently dry state to pulverize well.

On another part of the farm, which is nearly level, and where the soil consists, to a much greater extent, of loam and clay than the field I have just described, I obtained nearly thirty bushels of potatoes, and out of thirty bushels there were probably as many as one bushel of rotten ones. The land for these potatoes was also ploughed twice; and care was also taken to work the land when dry enough to pulverize.

From a part of the farm, which consists chiefly of a side-hill, of a loose gravelly soil, I obtained as many as seventy-five bushels of potatoes; and out of these seventy-five bushels there were probably not to exceed four quarts of rotten ones; and what rotten ones there were, were almost wholly on a part of the field which is nearer level than the rest, and where the soil consists, to a greater extent, of loam and clay than the other parts of it. The seed potatoes planted on the last mentioned piece were many of them of the same sorts as those which rotted so badly in the small and nearly level piece I have before described.

A part of the growing season of 1844 was unusually hot and wet. And these are probably among the causes why so many potatoes rotted that season. From my own experience, and from observations I made this season, (1844,) I came to the conclusion that light loose soils, and thorough ploughings, are among the best means of obtaining potatoes free from the rot. And at the same time it may be said, that rich soils with such management are well adapted to withstand any ordinary drought.

This season, (1845,) the disease among potatoes has assumed a somewhat different aspect in this region of country from what it presented in 1844. In many cases, the potatoes which at digging time appeared to be sound, have rotted after being buried in the field or put in cellars. And while I do not dispute that this result is in some degree attributable to the varieties of potatoes used for seed, yet my observation leads me to believe that much of it is to be charged to the wet, heavy state of the lands on which the crops were raised. And the following is one of my reasons for believing so:

This season I planted near one acre of potatoes on land which consists almost wholly of a light loose soil. The ground was ploughed three times before planting, which rendered it so finely pulverized that the heavy rains of the latter part of the summer had an opportunity to leach down so as not to remain in a superabundant quantity near the top of the ground. Out of this acre of potatoes there were probably not to exceed two quarts of rotten

ones; while some of my neighbors, who planted their potatoes on partially pulverized and wet, heavy land, had many of theirs rot, although they had, in part, the same kind of seed that I planted.

S. S. G.

SANDLAKE, N. Y., *November*, 1845.

From the Albany Cultivator.

MR. EDITOR: The potato disease occupies so much of the public attention every where, that the experience and observation of individuals may lead to a solution of this mystery.

Last year we lost but few by the rot. This year but few have escaped. We have lost upwards of 1,000 bushels already. I have examined the various fields about us, and find there is little or no perceptible difference as to soil. The disease has shown itself in every variety of soil in western New York where the potato grows.

Still I am not discouraged, nor do I believe there is any more danger of the extinction of the species than of wheat. My own impression is, that it is caused by the peculiar state of the atmosphere, and that the evil may be cured in two ways—

1. By early planting, and by using only the early varieties.
2. By cutting the stems or vines as soon as the blight or rust shows itself.

So far as my observation extends, the disease is analogous to the rust in wheat. It has been shown in a great number of cases, by actual experiment, that if wheat be cut as soon as the rust strikes the stalk, the loss is much less than when suffered to stand until it is ripe. If allowed to stand, the kernel becomes light and shrunken, yielding but little beyond bran. The disease appears in both instances in the stalk first, and the destruction of the farina in the tuber and the berry is but the result of the destruction of the stalk by the disease. It is a species of gangrene, which can only be arrested by severing the limb as soon as it appears. The remedy has been quite successful in wheat, and I have no doubt will be equally so with roots. I am the more inclined to this belief from an occurrence in my immediate vicinity. A neighbor had some potatoes planted in a very mucky piece of land, a reclaimed swamp; being in low ground, an early frost killed the vines. Some of his potatoes have rotted, while those near by, but upon drier ground, and where the vines were not injured by the frost, have been seriously injured. It was not the soil, for others in like soil, but not reached by the frost, have been destroyed. Again, our early potatoes which we grow in the market garden have not been affected; and generally the early varieties have suffered the least. I can hear of none that have been diseased where the vines died before the blight struck them.

It may be that ours is only an exception; I mention the facts for the purpose of drawing out others on the same subject.

My facts are truth; my inferences may go for what they are worth.

Sincerely yours,

T. C. PETERS.

DARIEN, N. Y., *December* 12, 1845.

From the Albany Cultivator.

THE POTATO DISEASE.

L. Tucker, Esq.: Facts being the very foundation of science, it has struck me that the following might assist some inquirer into the causes of the potato disease.

In 1843, the disease among the potatoes showed itself in this country. That year, in many parts of the country, the potatoes rotted in their bins, and it was found necessary to remove them. In 1844 the disease was more prevalent, while in 1845 it was much less extensive. In my own case, very little of the disease appeared among the potatoes raised in either year. Still, there was a little of it among the pink eyes in particular. Having observed that potato balls were very scarce in my own fields, and indeed in all this region, and being confident that the potatoes now raised in this country are much inferior to those raised five and thirty years since, I sent to England for seed. A friend was kind enough to obtain for me twenty-four hampers of fine Lancashire potatoes, last spring, which reached me just in time for planting. I had them placed in new ground, on the side of a field in which were planted pink eyes, trout, and orange potatoes. The yield of all the potatoes was light, on account of the drought, but the Lancashire did as well as could be expected. Four and twenty bushels of English potatoes were put away for seed in a cellar, under a hay mow, where the temperature is hardly above freezing; as good a place for the preservation of vegetables as could be selected. A quantity of the trout and orange potatoes were put in another corner of the same cellar. Fearful that the weather was getting too severe for my seed potatoes, as the mow grew thinner I ordered them to be removed last week to another cellar. On opening the straw that covered the heap, more than half of the potatoes were found to be far gone with the disease. As the rot has appeared in none of the other sorts that were grown in the same field, including pink eyes, I am left to infer that the English potatoes were infected, while the others were not.

I merely state the fact. The disease existing so extensively last year in England may possibly have some connexion with this loss; though, to connect the circumstances, it is necessary to believe that two seasons are required to develope the rot.

I will only add, that I had brought into my house some of the varieties that were grown, the English excepted, and I cannot find that a single potato has been affected. I know of no difference in the culture or land that should have produced this result. No manure was carted on any part of the field, though plaster was used throughout. As piles of logs and stumps had recently been burnt on the land, it is possible these ashes may have reached to these English potatoes, though not more so than to the others, as the log heaps extended over all parts of the field. I do not think, moreover, that the vines ever looked thrifty.

Yours, &c.,

J. FENNIMORE COOPER.

P. S.—It may be well to say that the English potatoes, diseased as they are, have been fed to store hogs, with perfect impunity. What is left of them seems to be as nourishing as the sound potato. They are affected with the black, cholera looking disease, and appear to moulder away, rather

than turn into a semi-liquid, putrid substance, as was the case with some grown in my garden in 1844.

HALL, COOPERSTOWN, *January* 6, 1846.

PREMIUM—DISEASED POTATOES—AMERICAN AGRICULTURAL ASSOCIATION.

At a meeting of the association, Monday, May 5th, the following resolution, offered by Dr. Gardner, was unanimously adopted:

Resolved, That this association offer a liberal premium for a series of investigations into the nature and origin of the disease of the potato, to be made under the conditions imposed by the executive committee.

The executive committee therefore offer, under the preceding resolution, a premium of $50 for the best investigations made during the ensuing season, in accordance with the plan drawn up by the chemist of the association, and appended. They also impose the following conditions: The competitors to be or to become members of the association; the papers and specimens to be forwarded free of expense to the executive committee, through their secretary, Dr. Gardner, 412 Fourth street, New York, on or before the 1st of November; communications, whether successful or otherwise, to become the property of the association; all persons in the United States may become competitors. The premium will be declared at the general meeting in January next. The papers sent to bear a motto, without the name or address of the author, these particulars being contained in a sealed letter superscribed with the same motto. Investigations terminating without the appearance of disease in the potato, but pursued in accordance with the ensuing conditions, will be received in competition.

The following conditions, to be observed by competitors for the premium of the association, are respectfully submitted by order of the executive committee.

D. P. GARDNER.

MAY 8, 1845.

1st. The papers to be entirely original, and in no part transcripts from other works; to contain a record of the observations made during the growth of the plants, and conducted on at least 150 specimens.

2d. The variety and character of the seed potatoes, the mode and time of planting, the nature of the soil, its condition of drainage, the manures used, and previous tillage, to be fully detailed.

3d. A daily register to be kept from the time of sowing to securing the crop, containing the temperature in the sun and shade, and the dew-point* in the shade at 12 o'clock, with the state of the sky, the occurrence of rains, dews, or other meteorological conditions. The manner of taking the dew-point to be stated.

---

*If the observer be not provided with an instrument for ascertaining the dew-point, the following simple method may be adopted: Let a little fresh spring water be placed in a dry wine glass and introduce a thermometer, stir it freely in the fluid, and ascertain the temperature at the moment the dew on the exterior of the glass is disappearing. If spring water be not cool enough to create a deposite of dew, add a few drops of iced water until dew is seen. The dew-point is the temperature at the moment dew first appears or vanishes; but the latter is the best time for examination.

D. P. G.

4th. Five entire plants to be taken up during each week after the third week from planting, and a record made of the condition of the leaves, stems, roots, and tubers, the last being cut open and carefully inspected with a simple microscope, and all unnatural appearances written down, with the day of the observation. Diseased proportions to be preserved by drying, and forwarded to the association.

5th. All insects discovered on the green portions, roots, &c., to be examined, and at least twelve specimens of each species in the perfect (imago) state to be preserved and forwarded to the association. When practicable, the caterpillar to be described or figured, and the habits of the insect recorded. This condition to be performed in the case of all insects whatsoever found preying on the herbage of roots.

6th. At least twelve specimens of tubers in every stage of disease, with a similar number in a sound condition of the same variety, to be forwarded. The leaves and upper parts of any plants presenting a remarkable appearance to be carefully dried between sheets of unsized paper, and at least twelve specimens sent, with all other objects, in the same box or parcel as the written communication.

From the Cultivator.

PREVENTIVE OF THE POTATO ROT.

Mr. Editor: It appears to me that the attention of your correspondents has been directed more to the *cause* or nature of the potato disease than to any specific remedy. Some have ascribed the cause to unusual dews, fogs, heat of the sun, small insects, or parasite mushrooms. We may, I think, safely conclude that the disease is entirely atmospherical, and as *inexplicable* as epidemics that affect the human or animal system. If so, then the only object would be to place the vines in a state in which they would not receive the disease. Thus the ravages of the wheat fly are avoided by sowing earlier than usual, and also rust in wheat by sowing early on elevated lands.

As it respects the numerous *preventives* that have been suggested, none of them appear to be of any general utility. The strewing on ashes, lime, or plaster; the cutting off of the tops; the drying them in the sun, before putting them into the cellar, are only laborious, and, at best, partial remedies. The suggestions of a gentleman from Virginia to plant early, and *at a certain depth*, on light, elevated soil, and to cover the vines two or three inches with leaves, would be, I think, of no general utility, except the early planting; for I find, by observation and extensive inquiries among farmers, that potatoes are affected in every variety of soil, and that every kind of potato is subject to the disease; that is, the same kind will be affected one year and not another, and on all varieties of soil. From these facts, I have concluded that it is not in the *kind* of potato or *state* of soil, but in the *time* of planting, or rather *state* of the vines when the epidemic appears.

Therefore, *assuming* that the disease is in the air, and that vegetables derive by far the greater part of their nourishment and substance from this element, I conclude that the disease is absorbed by the vines, *when* they are in a *state* to receive it, and by them conveyed to the potato among nutritious properties.

As to the time the disease appears, much will depend upon the temperature of the climate where the potato is planted, and the *period* of the maturity of the vines. In Vermont, I conclude that the disease appears from the middle of August to the middle of September, or *when* we begin to have heavy dews and damp, chilly nights. Then the leaves become slightly struck with rust or blight. This kind of weather produces rust in wheat. But the common potato rust, which comes in July or August, must not be taken for the disease, for rust of potato tops is not a new thing.

Now, in this region the tops of *early* planted potatoes generally become so far matured in the fore part of September that they cease to absorb the atmospherical properties. Hence, if this *transition* takes place before the disease has been conveyed to the roots, the potato is safe. I have been led to thus fix the time of the appearance of the disease from practical observation. I planted six kinds of potatoes on separate plats in 1844, all on good warm soil. Three of the kinds were planted about the last of April, and the others about the last of May. The *tops* of the first three plats were partially *dry* by the first of September; the others not until the first of October. The first plantings were free from the disease; the last were greatly affected by it. I tried the same experiment on six kinds last year, and the result was precisely as the preceding year. A neighbor planted the early kidneys in April last; the tops were dead in August. Some of the potatoes remained in the ground until November. They were perfectly healthy. He planted, from the *same* lot of seed, about the first of June, a small patch near his barn, the tops of which grew rank, and were green until killed by the frost in October. The potatoes were greatly diseased. Since then, I have ascertained that the tops of those potatoes that have proved to be diseased were generally green in September, or at least at the time of digging. It does not, however, follow that every field will be affected where the tops are thus immature. I have found two exceptions in fifty cases. In one case the potatoes were planted in July, and were so thrifty in September that the disease did not affect them. In like manner, human constitutions are not *equally* in a condition to take at one time the *same* disease. In the other case, the potatoes, being planted in a high, frosty region, were killed by a frost in the fore part of September, before the disease reached the roots. Hence very early or very late planting will escape the disease. But early planted potatoes are decidedly better for the table or for stock than late planted, unripe ones. Therefore let *all kinds* of potatoes, except those that are *very* long in coming to maturity, be planted early, (for the climate where they are planted) that the vines may partially ripen before the time of the appearance of the disease. It is no matter what the kind of soil is, or the kind of potato, if neither will greatly prolong the maturity of the vines. But avoid planting near barns, where the soil is exceedingly rich, or in low, wet places. Observe these rules, and we think that, in usual seasons, from 200 to 300 bushels of good healthy potatoes per acre will be obtained.

This process may also save the potato crop in Ireland. I am assured by emigrants that potatoes for the summer market are planted early, and are ripened in a pleasant, genial season, while those for winter use are not planted until May or June, for the sake of a long growth and a larger yield, which expose them to the disease.

KITTREDGE HAVEN.

P. S.—To have large thrifty vines in June, through the influence of spring or summer showers, spread in March or April your *entire seed* on grass plats the south side of buildings, and cover them with straw or blankets during frosty nights. The sprouts thus obtained will accelerate vegetation, while cellar sprouts retard it.

K. H.

SHOREHAM, VT.

From the American Farmer.

Experimental report to the Maryland Farmers' Club, on the potato disease: by Daniel Bowley, Corresponding Secretary.

Numerous and conflicting as are the arguments which have been recently held in the various attempts to discover the *nature* of the disease in the potato now prevalent, and if detected, what *remedy* could be effectually applied, the majority, both as regards authority and number, have satisfactorily established the fact that it is a fungus of an excrescent or parasitic character. Equally well sustained have been the numerous assertions that a remedy has been successfully applied.

The most authentic paper on the subject which has fallen under my observation, among some hundreds, is the report by C. Morren, Professor of Agriculture in the University of Liege.

Imperfect in idiom, as is every translation from the German into the vernacular, it covers the whole ground, exhausts the controversy, and, in accordance with my own *experience*, establishes the main practical facts essential to the producer's safety.

Before departing from my allusion to Professor Morren's able report, I think it necessary to contest an error into which certain late writers on the subject have unwittingly fallen.

This peculiar distemper, like all other important facts, has its history. In Mexico and South America, where the tuber is indigenous, it has always been known as an epidemic, recurring at irregular periods, and eccentric in its progress.

The terms *epidemical*, *contagious*, and *infectious*, are often confused in their application, even by the medical profession. In the report alluded to, the word *ansteckung* is rendered *infection*, being literally "*stuck on*," or *extraneous*, from the verb *anstecken;* while the German equivalent for *epidemical* is *ansteckkend*, and *contagious* is expressed by *ansteckend ;* so that this word, as used by Professor Morren, embraces the whole sense of the three words, in their widest construction, and he pronounces the potato disease, after the most skilful and patient examination, to be of this character.

In our own language, we understand that whatever is *prevalent*, is, *where* it is so, epidemical. Certainly no one at this advanced stage of the discussion will assert that the potato disease is not *prevalent! Infectious* and *contagious* convey almost precisely one meaning, commonly called "*catching*." My own observation, as regards the tubers after housing, is, that this disease is *all of these*, in their fullest sense.

Relying upon the usual supply from the east for my seed potatoes, I had

disposed of my own crop, and purchased thirty bushels for early planting, of blue Maine mercers, at the wharf. This was the middle of February last; but before planting time arrived, nearly one-third of that quantity had decayed, although they had frequently been picked over. When purchased, a scarcely perceptible scurfy gangrene, in spots, had made its appearance on them.

Ten bushels were cut and planted on the seventh of March, in strong alluvial soil, in drills, *under* fermenting stable manure; the pieces, immediately on being cut, were dried or healed in a compost of two parts each of plaster (sulphate of lime) and leached ashes, to one part old slacked (carbonate of) lime.

The memorandum in my diary reads thus:

1845, March 7. "Planted early potatoes across run; pieces cut large; dried in plaster, ashes, and lime, and planted under horse manure."

March 25. "Planted five bushels potatoes near poultry yard; the eighth row from the east side without manure, to be guanoed when up; the rest planted *on* long green manure; all in drills; pieces six inches asunder."

The yield of this first planting was very good, notwithstanding the drought, but, being very early, were sold in market; the latter not so well, the guanoed row excepted, which yielded equal to the first planting, or one-fourth more than the second.

There was also another small planting, besides the "crop;" a sample of the last I now hand for the inspection of the club, which they will perceive are in a perfectly sound condition.

I have cited from my diary thus minutely, to correct two errors almost as much prevalent as the disease. The first, that the kind of manure produces the fungus; the second, that it is the nature of the soil, combined with or arising from the humidity of the atmosphere. Now my several plantations were in all the varieties of soil, except stiff clay, and in all manner of exposures, from the hill top to the ditch level.

Undoubted authority overthrows a third error—that is, that the wetness of the season, combined with a sultry denseness and other atmospheric phenomena, generate the mushroom. A friend of mine, a member of this club, lost his whole crop of last summer's growth, whose place is but five miles distant from mine, inland, and some hundreds of yards higher above the marine level, the seed being of his own growth, and apparently perfectly sound.

In fine, gentlemen, not one diseased potatoe have I yet seen in my crop, although the seed from which they were grown was corrupted, and the old-fashioned stimulants, except in the one instance, were used as manures; so that, in the absence of any antagonist principle, I must consider this chemical compost not only a remedy, but a preventive of the epidemical potato fungus.

FURLEY HALL, 1846.

From the American Farmer.

THE POTATO SICKNESS.

Correspondenee between Mr. Peter, British consul at Philadelphia, and Mr. Gowen, of Mount Airy, on the subject of the potato rot.

[Mr. Gowen's reply]

MOUNT AIRY, *December* 29, 1845.

MY DEAR SIR: Your note on the subject of " the potato rot," dated Saturday, did not reach me at Mount Airy (Sunday intervening) till this morning, Monday. It would give me pleasure to oblige you fully in this matter, did time permit to go more into detail; but the brief space allotted for a reply will compel me to be as concise as possible.

I hold that atmospheric influence is the sole cause of the late pervading rot in the potato; that neither manures nor condition of soils could have produced the calamity; that animalculæ and fungi are as remote from it, (the latter may in a partial manner injure a potato plant,) as they would, under peculiar circumstances, be likely to injure other plants; that the rot is *not* epidemic; and I have reason to believe that sound or *partially* sound potatoes, taken from a diseased crop or heap, will, if planted, produce healthy, sound potatoes, in the absence of the cause which injured them the previous season.

I would, therefore, encourage the farmers to cultivate their potatoes as formerly, choosing the soils and applying the manures which hitherto were found best adapted to their culture; forgetting or overlooking the rot altogether, and disregarding the nostrums recommended for its prevention: the potato won't bear doctoring.

The weather which produces rot is either a severe, continuous drought of some weeks' standing, thereby preventing the natural growth and maturity of the potato, for the want of moisture, or very hot weather, bringing the potato to a premature ripeness, succeeded by wet, sultry weather, unnaturally *spring-like*, which provokes the tubers to perform the functions of seed, thereby dissolving the connexion between them and their vines: the vines die; the roots undergo an incipient fermentation preparatory to decomposition; the operation of budding or growing is checked by the natural autumnal temperature that at length prevails, which arrests the potato in its work of producing; and hence its deterioration. The latter condition of the weather is the prevailing cause of the rot.

As to a severe and continuous drought, my own experience points to that of 1838. That season I had a five-acre patch in with potatoes, which did not pay for the trouble of taking them out of the ground. They were small, ill shaped, bad tasted, poisonous, spotted, and black-hearted, and rotted in the cellar. Potatoes that season sold as high as $1 25 and $1 50 per bushel; not a bushel of good potatoes at market except those imported. Then as to dry, hot weather, succeeded by wet, close, over spring-like temperature, the season of 1843 is in point. I took more than common pains that year to produce a surpassing yield—equal, at least, to my famous crop of the preceding year, which was over 440 bushels to the acre, field culture. My seed was in part from those fine potatoes, and in part from some very large, sound potatoes imported from the State of Maine. On taking out the crop in October, the whole was found to be very badly diseased. The weather from the latter part of June, till the beginning of September,

was mainly hot—occasionally very hot and dry. September set in with warm rains, thunder storms, and gusts; the moisture and closeness unprecedented. Fruit trees blossomed, as well as many flowering trees and shrubs. I recollect making a large collection of flowers from the magnolias, some of which I sent to the editor of the "Pennsylvania Inquirer." My potato vines looked green and healthy; when, all of a sudden, they changed color, drooped, and died. I think if I had taken out the potatoes at that juncture they would have proved comparatively good; but they were permitted to remain quite a month after, when they were found badly rotted, tainted, and almost worthless.

Now, then, as to the epidemic. In 1844, I planted some four to five acres of potatoes, *the seed of which was principally culled from the diseased crop of* 1843. I planted, also, at the same time, in the same field, other seed of very sound potatoes brought from Maine. They all did equally well. *I could discover no difference.* The crop was a very fair one, and the quality unexceptionable in every respect. I do not mean by this to encourage the planting of diseased or doubtful potatoes. It is safer to plant sound and perfect ones; but I am strong in the opinion that there is no danger of a diseased or tainted potato *producing* a diseased or tainted potato. It may, from its want of vitality, be very unproductive, make feeble shoots, the same as decayed potatoes from on shipboard, after a long voyage; the heat and moisture of the vessel's hold having caused them to send out enormous shoots, impairing their vigor, and producing rot. Such potatoes, when planted, never produce well as to size and quality; but I have yet to learn that they ever produced a diseased potato.

Much has been said of potatoes becoming feeble and sickly from long and constant planting. There may be something in this; time will not permit me to examine it now. I have, however, numerous sorts of seedlings produced from the apples of my very fine crop of 1842. I shall take occasion to present you with a few to send to some of your friends abroad.

By this you will see that I can offer no remedy or preventive for the rot. He that tempers the winds to the shorn lamb can only control it. Should it again visit us, we can only exercise our best judgment by taking out the potatoes early—as soon as they exhibit signs of decay; laying them in thin layers, in dry, cool situations, or otherwise, as circumstances may justify. Let the farmers go on and plant in confidence, as their best experience may teach, trusting, for the abundant yield, to that Providence who sendeth the early and the latter rain.

Very respectfully, your friend and obedient servant,

JAMES GOWEN.

William Peter, Esq.,
Her Britannic Majesty's Consul, Philadelphia.

APPENDIX No. 6.

POTATO ROT IN EUROPE.

From the (London) Gardeners' Chronicle and Agricultural Gazette, of Aug. 16, 1845.

POTATO BLIGHT.

A blight of unusual character, which almost invariably affects the potatoes in this island, having been the last few days brought to my notice by several gardeners, I am induced at once to lay before the readers of the *Chronicle* such observations as I have yet been able to make on the subject, being desirous to know whether this plague be in reality, as it is here supposed, an entirely new one; whether it be local or general in other parts of the Kingdom; and principally, and lastly, what is the best course to pursue where it has made its appearance. The first appearance is a dark spot on the margin of the leaf, which withers the leaf, and spreads rapidly to the stem. The discoloration soon extends along the stem in the course of the vessels, and the whole plant rapidly becomes black, so that within three days after a plant is attacked it has become totally destroyed. With this appearance in the upper part, there co-exists a fatal change in the tubers: they become likewise spotted, at first, near the eyes on the upper surface; the cuticle separates, the substance becomes friable, and the change soon spreads throughout the whole potato. All situations, whether high or low, and whatever the nature of the soil, appear to be equally visited. The attack on the plant appears invariably to commence in the leaf, and not in the stem; and the spot commences at the margin, corrugating the leaf as it spreads. It is black on the upper surface, but on the lower surface, though black in the centre, it is whitish or gray in the margin, but neither minute insects nor fungi can be seen with a strong lens. That, as regards the green portion, the leaf is affected before the stem, I am quite clear; but the question arises, is the disease in the root and tuber the cause or consequence of the above change? I believe the latter to be the case, from all the instances I have examined; and in one instance in particular, where from ripeness the greens were on the point of withering when attacked, the affection did not at all extend to the roots. The change which takes place in the tuber is as follows: The first appearance resembles a severe burn; the root turning gray or ash-colored, and the cuticle coming off. When the change has become considerable, I am told that the vegetable has a pungent and nauseous taste, and it is reported to have been injurious to pigs; but on this point I have no certain information. So universal is the evil that the consequences are likely to be very serious, as, in a long journey on horse-back, I have this day carefully watched every potato ground as I passed along, and not one could I see uninjured

T. BELL SALTER, M. D.

ISLE OF WIGHT.

From the Mark Lane Express

But the great distress of the farmer is the total failure of the potato crop. Up to Monday last the promise was the most abundant ever known—the

whole looked healthy. In one night the mischief was done; the whole of the stalk and leaf turned as black as your hat, and the potatoes rotted in the ground. This is a sad state of things; and the general opinion is, that sufficient will not be saved of the crop for seed. A friend of mine has just returned from a visit in France. He says, in the whole of Normandy and Brittany the crop is a total failure—the damage done in one night. They attribute it there to frost. Here the farmers say that after heavy rain, and so long continued, and hot weather set in, the ground heats the potato. I believe this to be true, as it begins to blacken at the foot of the stalk. It has been very hot to-day; the farmers fear, from the great heat, the grain will shrivel much.

GUERNSEY, *August* 16.

From the Gardeners' Chronicle, August 23, 1845.

A fatal malady has broken out among the potato crop. On all sides we hear of the destruction that has overtaken this valuable product, excepting in the north of England. In Belgium, the fields are said to have been entirely desolated. There is hardly a sound sample in Covent Garden market. In fact the murrain seems to have been transferred from cattle to potatoes.

Dr. Bell Salter last week called attention to the symptoms of the disorder as manifested in the Isle of Wight, and we this week print many other communications on the subject, concerning which we have very numerous letters. The disease consists in a gradual decay of the leaves and stem, which become a putrid mass, and the tubers are affected by degrees in a similar way. The first obvious sign is the appearance, on the edge of the leaf, of a black spot, which gradually spreads; then gangrene attacks the haulm, and in a few days the latter is decayed, emitting a peculiar and rather offensive odor. When it is severe, the tubers also decay; in other cases they are comparatively uninjured.

The cause of this calamity is, we think, clearly traceable to the season. During all the first week of August, the temperature has been cold, from two to three degrees below the average; we have had incessant rain, and no sunshine. It is hardly possible to conceive that such a continuation of circumstances should have produced any other result, all things considered.

The potato absorbs a very large quantity of water. Its whole construction is framed with a view to its doing so; and its broad succulent leaves are provided in order to enable it to part with this water. But a low temperature is unfavorable to the motion of the fluids, or to the action of the cells of the plant; and, moreover, sunlight is required in order to enable the water sent into the leaves to be perspired. In feeble light, the amount of perspiration from a plant is comparatively small; in bright sunshine, it is copious; in fact, the amount of perspiration is in exact proportion to the quantity of light that falls upon a leaf. At night, or in darkness, there is no appreciable action of this kind. During the present season, all this important class of functions has been deranged. The potatoes have been compelled to absorb an unusual quantity of water; the lowness of temperature has prevented their digesting it, and the absence of sunlight has rendered it impossible for them to get rid of it by perspiration. Under these circumstances, it necessarily stagnated in their interior; and the inevitable

result of that was rot, for a reason to be presently explained. If the first days of July had not been suddenly hot, it would not have happened; if we had had sunlight with rain, it would not have happened; and perhaps it would not have occurred had the temperature been high, instead of low, even although the sun did not shine, and rain fell incessantly. It is the combination of untoward circumstances that has produced the mischief.

Although we first see the symptoms of the disease in the leaves, and then in the haulm, yet we believe that it commences under ground, in that part of the haulm which is just above the old set. There, water collects the most; there, the temperature is lowest; and there, the old set itself, acting like a sponge, and itself decaying, feeds the live stem with semi-putrid matter.

It may be urged, perhaps, in opposition to this explanation, that potatoes thrive very well in districts whose summers are usually as unfavorable as this has been; as, for example, the cold parts of Scotland. And that is doubtless true. But in those climates the potato grows slowly; its tissue becomes thoroughly organized as it proceeds, and it is not liable to be acted on by accumulated moisture. There, no predisposing cause exists. But in England, the potato was predisposed to take the disease which is destroying it, by the unusual warmth of the beginning of July suddenly succeeding a period of cold, ungenial weather; at that time the temperature of the soil near London was between 60° and 68°; the potatoes grew excessively fast, their tissue was soft and unconsolidated, filled with azotized matter, as all such tissue always is, and peculiarly liable to run into a state of rottenness. They have never had the means of consolidating their tissue, but the tendency to putrefaction has continued almost unchecked ever since the sixteenth of July, when the cold and unfavorable weather first began to declare itself; the tendency has increased, and at last accumulated so far as to terminate in absolute decay. This is strikingly illustrated in those cases where, in consequence of the badness of the soil, the potatoes made no considerable progress in July, but continued stunted and unpromising, notwithstanding the warm weather. In such places—and we have one beneath our eye—not a trace of rot is to be found.

The mischief, although very general, is not universal. It is, however, appearing in some of the gardens around London; and it has begun to attack a field near ourselves, on the London clay, which, as it offers what we think a good illustration of the way in which the potato crop is affected by such a season as this, we shall proceed to describe. The field is bounded on two sides by a deep ditch, newly cut, and on the others by a hard roadway. It was last year a pasture. During the autumn, it was trenched three spit deep, but in such a way that the turf was turned down about a spit below the surface. It was planted partly in December, and partly in April. Here, on this cold soil, lying on a dead level, with scarcely any means of effectual drainage, the potato murrain might have been expected; and here it has made its appearance, but not to any great extent. Symptoms are discoverable here and there; but only in one place has the haulm actually decayed. That place was a low part of the field, and had been made up with road sand and similar rubbish, very retentive of water. Elsewhere the leaves are yellow—an invariable symptom of an over-cold and damp land. In situations better drained, as, for example, all along the ditch, the foliage is green, vigorous, and healthy.

Here, then, we find what we look upon as good evidence of the justice

of the opinion which we have ventured to express as to the cause of the pestilence in question. The whole crop is not attacked, because, although the land is ill-drained, yet the recent trenching, and the decaying turf just below the potatoes, have been sufficient to carry off the water. Where it was otherwise, (that is, where road sand was thrown down to some depth, and consequently the turf drainage annihilated,) there, and there only, the disease appears.

We should be much obliged to our correspondents if they would examine closely into the state of the ground where their potatoes are growing; for if water lodging in the ground is the cause, then thorough drainage will be the preventive in future years. That excessive wet, in a cold soil, is the cause, connected with the other circumstances already alluded to, is, we think, conclusively proved by potatoes from Bennenden, in Kent, which are half rotten. Now these potatoes had already burst, from the quantity of water they contained; but the wounds so produced had healed up, and now they are perishing from murrain. We infer, from these examples, that at Bennenden, even in the warm and comparatively sunny days of July, the tubers were injured by excessive wet; but, on that occasion, it did not end in putrefaction: that form of the disease did not come on till the cold, gloomy, watery days of August, and after the forced growth of July.

Since writing thus far, the post has brought a fresh supply of information—among which are letters from Dr. Bell Salter and Mr. Gifford, a Jersey gentleman. The former states that the disease has become modified, and ceases to run its course so rapidly. During the last week we have had a little sunshine, and a cessation of rain. Mr. Gifford's remarks coincide with the views above expressed.

As to cure for this distemper, there is none. One of our correspondents is angry at our not telling the public how to stop it; but he ought to consider that man has no power to arrest the dispensations of Providence. We are visited by a great calamity, which we must bear. At the same time, although it is not within human means to alter the course of the seasons, or to prevent the maladies attendant on them, yet prudence may perhaps suggest some alleviation of the evil. Should we have fine weather, the disease will probably disappear; should rain and cold continue, it will spread. In the latter case, the only thing to be done will be to dig up the crop immediately. Much loss will be thus sustained, and the quality of late potatoes will be bad; but the loss will be less than to let the potatoes all rot in the cold ground; and we conceive that some of the crop will be eatable, though not what could be wished. We find that, in some districts, the haulm has been mowed down by way of stopping the mischief, (and this may be judicious as a temporary expedient;) but we fear that no real advantage can be expected from any other course than digging up, drying, and sorting over the produce.

Although the potatoes taken up thus early will suffer in quality from their unripeness, yet even this evil may be partially remedied by putting them in heaps consisting of alternate layers of dry earth and tubers. In such a situation it is probable that no further decay will take place; and it is certain that the ripening process will continue to proceed, although less effectively than under natural circumstances. We may add, that such late potatoes as we have examined are much more advanced towards ripeness than might be supposed. They are already very full of starch, and their gummy matter is disappearing fast.

We should be very glad to know how far the observations of others confirm or contradict our suggestion, that thorough drainage prevents the appearance of the potato murrain. We should also wish to know whether it has appeared in the cold parts of the Kingdom. If not, the potato harvest in the north bids fair to be as profitable to the gardeners there, as it is ruinous to those in the south; and holders will do well to ascertain the value of their potatoes in London before they sell.

As to the fitness of decayed potatoes for food, we doubt extremely the prudence of using them, if the disease is more than skin deep, so that it may be pared away. Putrid matter of any kind (or even matter approaching putridity) is unfit for being introduced into the stomach, and has very often proved fatal. The Belgian police, acting upon this well known fact, have been destroying the decayed potatoes in the public markets of Antwerp; and they have acted wisely.—[*Editorial.*]

From the Gardeners' Chronicle, August 23, 1845.

I am sorry to say that the pestilence mentioned by Dr. Salter, which has seized the potato crop in the Isle of Wight, has also done a deal of damage to our potato crops in the island of Jersey; but, thank Heaven, not as yet to the extent mentioned by your correspondents. About three weeks ago I first perceived the mischief in a potato field of mine, (about an acre,) and I at once attributed it to the easterly winds, and took no more notice of it; but a few days after, seeing the fields of my neighbors in the same plight, and having taken notice that those parts of the fields which were most sheltered from these winds had not escaped the disease, I concluded that it must be attributed to other causes, as yet unknown. Having remarked that the places most affected were under the hedges and in the coldest parts of the fields, where the sun had less power, and that those parts where the sun had full play the crop had suffered less, I think that it will be found, after a serious investigation, that a great deal of the mischief must be attributed to the very wet season, and to the cold nights which we have had all through the summer. With us, the tubers have not yet suffered. I dug a few roots the other day, and though unripe, they were found very good. So far as the leaf and the stems go, the disease seems to be the same as mentioned by Dr. Salter, and it seems to be universal through our island.

RICHARD GIFFORD.

JERSEY.

P. S.—I have potatoes in a field (hilly ground) where the sun strikes all day long, which shows no symptom of the disease; and this, according to my opinion, goes far to prove that the state of the atmosphere through the summer has had a great deal to do in bringing the dreadful calamity complained of.

R. G.

The perusal of the article on potato blight induces me to trouble you with a few remarks on the subject.

About ten days ago, I first noticed a brown spot or mark on the margin of some of my potato leaves. On examination, I also found spots of a similar color on the stalk; but on trying the roots or tubers of several sorts, I could find no perceptible disease or injury. This morning I have been induced to examine a variety of sorts in different situations and soils: 1st, ash-leaved kidneys; 2d, Julys; 3d, Fox's or Cox's seedling; 4th, peeler; 5th, Lancashire red; 6th, Canada pine; 7th, a potato kindly sent me by Dr. Henderson; and, 8th, mangel-wurtzel. All the sorts, in all the situations, appear to be similarly affected, except number 8, which has up to this day almost entirely escaped, though the fatal spot is occasionally perceptible on the leaf, the plant growing very luxuriantly. I may add that every plot in my allotment field, under every variation of culture, is in the same sad condition, and the neighboring farmers make a similar report. I observe here that the centre of the plots has been first affected; that haulm smells remarkably like new made hay, and the whole of the mischief above ground is done in the course of three or four days. I cannot, however, ascertain that as yet any injury whatever has been done to the tubers in either of the sorts I have mentioned, whether early or late. It is true that I found a few of my Julys slightly diseased on the outside, but not more so than frequently happens, and certainly not sufficient, *per se*, to attract notice or remark. My gardener calls the disease the dry rot.

PETWORTH.

From the Gardeners' Chronicle, August 30, 1845.

Another week has added little to what we know about the *potato murrain*, but that little is important.

In the first place, we appear to have been right in supposing the distemper to have confined its attacks mainly to the southern parts of the country. We hear nothing about it in the north, and Mr. Berkeley writes that he cannot find a trace of it in his part of Nottinghamshire.

As we anticipated, its virulence, too, seems to have abated, and we feel warranted in the hope that the worst is over; that is to say, that no more tubers will be attacked than those in which the distemper has already manifested itself. But we fear that their number is far beyond what is imagined. It is certainly greater in the places we have personally inspected than we anticipated. We have this morning been examining a field in which the pest has assumed a comparatively mild form, and we find that among bread-fruits six in nine, among Jersey blues all or nearly so, and among Dr. Henderson's black Scotch potato a large proportion, indicate unequivocal signs of its presence. It is not, however, easy to discover it in the dark-colored potatoes without cutting them, and therefore we speak doubtingly as to them. In the bread-fruits it appears in the form of dull, livid patches or specks, looking much like contused flesh, or, to use a familiar comparison, like the skin round a blackened eye when it is beginning to recover its natural color. This appearance is, however, not to be seen plainly, unless the potatoes are washed. A little earth, or even the skin adhering to the potatoes, hides it; and this deceived us on our first inspection.

We fear that every potato which is affected, in ever so small a degree, is lost; for we have too much reason to believe that the disease is of the nature of a canker, eating down into the flesh. At least, we find that pota-

toes which a week ago were taken out of the ground and placed in the dark, on the floor of a dry stable, are infinitely worse than they were. It is this which leads us to suppose that every potato, in ever so small a degree touched, will rapidly decay. This is unfortunately rendered the more probable by the appearance of a kind of mouldiness, mentioned elsewhere by Mr. Berkeley, which appears on the cankered spots, and which will no doubt add greatly to the mischief, though we are quite persuaded that it is the consequence and not the cause of it.

The cause is, we think, beyond all doubt that which we last week suggested—excessive wet, and a low temperature, acting upon the debilitated organization of a haulm, which sudden warmth had forced into preturnatural vigor. Some of our correspondents think, indeed, that the spot in the leaf is the cause ; that it is cold, or some other thing, acting upon the foliage, which has caused a disease which spreads downwards. If we may be certain of any thing, when considering the obscure phenomena connected with vegetable disease, we may be certain that this is not so. The evil always begins next to the old set, and under ground ; then the haulm becomes brown, and rots. The spots in the leaves are merely the symptoms of the under-ground malady. It is only necessary to take up a few patches of sound and unsound potatoes to be convinced of this. In fact, in some places it will be found that when the attack on the stem beneath the ground has been slight, no indication of its presence is traceable in the foliage. We suspect, indeed, that in every case the potato straw has been damaged above the old set ; for where potatoes are perfectly sound they now seem to have little communication with the parent—to have ceased growing ; and the sound parts of the haulm are here and there throwing out a fresh crop of potatoes, now about a week old.

Of course the grand point to settle is, what can now be done? When the mischief is severe—nothing. We should abandon the crop to its fate, and plough up the field if time will permit. This is, however, not very important, because we do not apprehend that the rotten potatoes will leave any contagion in the ground, *unless it be for another crop of the same kind.* We certainly should not like to grow potatoes in such fields next year ; otherwise, we presume that the decayed tubers will act like any other decayed matter, and manure the land.

Is there any gain in mowing off the haulm that remains, when the disease is less severe ? If we thought that such haulm was at all in communication with the potatoes themselves, we should say, cut it off by all means. But the cords of union are apparently broken ; and if so, there seems at first to be no advantage in removing it. If, however, what remains of the foliage is still in communication with the sound potatoes, it will affect them, and therefore, perhaps, it is a wise precautionary measure to mow the haulm down. Its remaining can do no good ; and at all events, cutting it off will do something towards enabling the ground to become dry.

* * * * * * * * *

Upon the whole, we suspect that the potato growers will be compelled to leave their crops to their fate until harvest is more advanced.

Can the decay be arrested in those potatoes in which it is now manifesting itself? That is another and most important inquiry, to which the novelty of the distemper renders it impossible to give any thing more than a conjectural answer. For ourselves, we fear that external applications, like

lime, whitewash, or charcoal powder, will be inefficacious—for this reason, that the disease cuts into the core of the potato, and the action of all such substances, if of any advantage whatever, will be merely on the surface.

* * * * * * * * *

Suppose that infected cankered pieces were cut out, and the wound dressed in quick lime or whitewash; would that stop it? The plan may be tried. One thing, and one only, strikes us as a probable remedy, and that is, destroying the vitality of the potato by driving off its moisture. This may be done by kiln-drying, and we fear by no other means. It might be worth the while of those who have the means to try this experiment, and if it should produce any advantage this year, it may be useful to know of it in case we should again be exposed to such a melancholy visitation.

* * * * * * * * *

If it is any consolation to potato growers to know that they do not stand alone in their misfortune, we can add that acres of pickling cucumbers have gone off in the same manner, from the same cause, and with the same symptoms. We have now before us a gourd, whose roots and main stem seem to have perished about a month since; but the plant has not died, because the succulent stems have thrown out fresh roots from the joints. The same thing is happening to potatoes, but, from the lateness of the season, we fear to no practical purpose. * * * [*Editorial.*]

We find the potato crop in this neighborhood (Havant) is also affected, but not to so great an extent as your columns describe the injury to have been in the Isle of Wight. On digging up the roots, the tubers nearest the surface of the ground are, in general, the only ones affected, though in some plants the injury extends throughout the potatoes belonging to that root; but where it does not so extend, the rest of the tubers appear perfectly well grown and healthy. It certainly is not a disease of the root, but appears to be the consequence of injury done to the haulm and leaf. Is not the cause to be attributed to the severe winds and white frosts experienced a short time ago injuring all above the ground, and preventing the vessels of the plant from drawing up the juices from the roots, and these tubers, full of stagnated fluid, immediately decaying? Supposing this to be correct; I have practised the cutting off the haulm, with a reaping hook, about one inch between the earth, into where the frost and winds might be supposed not to have injured the vessels of the plants, hoping by these means to induce them to bleed, and thereby relieve the tubers of their stagnated fluids. This is not capable of curing the injured; but it might probably prevent other tubers from becoming affected. I also suppose that if nature form a leaf from this proceeding, the potato will certainly be saved; and if a leaf be not formed, then, by leaving the potato an extra time in the ground, the tubers not affected might ripen and become wholesome food; which they cannot be if not allowed to fully ripen.

H. S.

I have reason to believe that you are perfectly correct in ascribing the potato disease to excess of moisture in the plant, consequent on the late

continual rain and absence of sun-light, and that it has been greatly aggravated by a too retentive soil. Our garden is, from its locality and the nature of its sub-soil, so thoroughly drained, that in most summers we suffer excessively from drought; and, though the haulm of the potatoes grown in it is more or less affected, the tubers themselves are comparatively uninjured; while in a piece of ground apart from the garden, having a stiff clayey sub soil, the disease has been much more violent. I am also inclined to agree with you in connecting with the disease the sudden heat of the end of June and beginning of July, as in a piece of Dutch potatoes, which was not planted before that time, scarcely a symptom of the disease is perceptible. I may also remark, that, in the garden, the disease originated in a part of the potato ground which is shaded by a large apple tree, so that for a time the outline of the blackened haulm exactly represented the shadow of the tree.

OXON. E. J.

I have this morning received from Dr. Montagne, of Paris, some leaves affected with the mildew, together with an admirable analysis of it, and it proves to be a minute mould of the genus Botrytis, very greatly resembling that which is so very common on the Shepherd's Purse, especially on those plants which are attacked by the white uredo. It is also allied to Botrytis destructor, (Beck,) which is occasionally a perfect pest amongst the different species of allium. I have seen whole beds of shallots entirely destroyed by it, and it is occasionally very prejudicial to onions.

The parasite of the potato does not appear to have been observed before by systematists, and differs in several particulars from those of the same genus which have been long known as attacking the leaves of various plants. Dr. Montagne purposes to call it Botrytis infestans, and will doubtless take an early opportunity of publishing his observations. He does not undertake to say that the spots on the tubers are owing to the ravages of the Botrytis, or whether two causes of disease co-exist. The primary cause is doubtless the continued wet, combined with certain peculiarities of soil. It may be observed that the dry rot in potatoes, so ably described by Martius, arose from the attack of a fungus of a very different structure from that by which the leaves and stems are attacked in the present instance.

KING'S CLIFF, *August* 26. M. J. B.

From the Gardeners' Chronicle, September 6, 1845.

Since I last wrote to you, I am sorry to say that the potato murrain has made its appearance in Northamptonshire and the neighboring parts of Huntingdonshire, and is spreading very rapidly, and will, I fear, do great damage unless the improved state of the weather checks the evil, about which I am not very sanguine. I have seen it on various kinds of soil, and on both early and very late planted potatoes; on some, indeed, which are now in full blossom. It is quite as virulent on well drained fields, whether the soil is bad or good, as on the cold, undrained clay of our forest land. The worst case that I have seen is in Huntingdonshire, on an

excellent piece of well drained land, but lying within a few yards of the river; not, however, subject to be flooded. I do not find that the tubers are at present affected; but the haulm is decaying very rapidly, and in every case the blighted spots are covered with Botrytis infestans, (Mont.) You will be interested to learn that the mould on the potatoes which you sent me is identical with that upon the leaves, and the same with what I have received from Paris. On making a very fine vertical section through the less diseased portion of the tubers, I find incipient plants of the mould in the more healthy cells; for, in general, the brown spots do not at first consist entirely of decayed cells, but still retain many in a tolerably healthy state. At a later period, probably, all the cells would be more or less altered. Those which are uncolored exhibit their usual appearance; but the walls of the diseased cells are thickened, and have a granulated appearance. Both in colored and discolored cells the grains of the fecula remain apparently unaltered, and are as sensible to the effect of iodine as ever. It is probable, therefore, that at least in an early stage of the disease the tubers would yield as good starch as those which are sound. There is not the slightest appearance of any processes upon the grains of fecula, as in the disease so admirably illustrated by Martius. It is the cellular tissue alone which seems to be affected. The cells immediately beneath the cuticle, especially where there is a depressed spot externally, are often impregnated with mycelium to such a degree that the pure white of the mycelium predominates, and the brown tint in a great measure vanishes. Even in this case I find the grains of fecula healthy and abundant. It appears, then, that the decay of the tuber is produced by the same cause which affects the leaves, viz: by the growth of a mould whose development has been promoted by the excessive wet. The parasite does not appear to have been observed before; but there is little doubt that it will now be found to be more or less prevalent in damp and ill-drained spots, even in the driest years.

The execessive development of the mould, and its consequent injurious effects, depending entirely upon the season, it will, beyond doubt, be impossible to find a remedy; nor does it seem, from what has been stated above, that even the best cultivation will insure exemption. It is greatly to be desired, that as such points are seldom if ever taken in hand by government, some of our agricultural societies would, from time to time, take proper steps to insure the best information possible as to the extent and circumstances of any plague like that which is at present so injurious. The most valuable facts are thus obtained upon the continent, when the commissions are properly instituted; and in some cases, as in that of the calamity by which the vines of France were for some time affected, such inquiries have been attended by the most beneficial results. It is impossible, from any number of independent documents, to arrive at the complete history of any disease like the present. A continued series of observations, conducted both by practical and scientific men, and thus embracing every possible point, and extending through remote districts, with the power of comparing individually the different phases it exhibits, or the varied circumstances under which it appears, can alone lead to any thing satisfactory. The expense, doubtless, would be considerable; but the utility, whether immediate or more remote, would be fully commensurate with the expense.

M. J. B.

King's Cliff.

In reference to your remark, that the disease commences under ground, I must beg leave, though no physiologist, to doubt it. I have in very many instances split or divided the haulm from the blossom to the root; and in only two instances did I find any defect below the ground. Both these were in the Julys; the outside appearance was that of mildew; the stalk at the lower end, both above and below the surface of the ground, was dry, wiry, and scarcely flexible; but this occasionally happens in ordinary seasons. I have found only one instance of the disease having penetrated the haulm more than skin-deep, without destroying it; in this case, it assumed the appearance of a reddish-brown canker. My observations would not lead to the inference that well drained land has in any material degree escaped the scourge, and I feel fully justified in making the remark, from the very porous character of the soil around me, and my knowledge of the manner in which a large portion of it has been cultivated. It is a somewhat remarkable circumstance, that on Friday, the 8th of August, we had an unusual quantity of electricity in the atmosphere, and lightning from all parts of the heavens. We had also three nights consecutive frosts at that time; and on Saturday, the 9th, the disease was first noticed in this neigborhood. I do not pretend to infer that electricity has introduced this disease; but, as the coincidence occurred, I have thought right to mention it. I am disposed to attribute the mischief to the cold, wet, and generally ungenial season, and perhaps to our want of sufficient knowledge of the habit of the potato. Is there any thing in the nature of the mangel-wurtzel potato different from that of other kinds, or is my observation in its favor a solitary testimony?

H. H.

Petworth.

—

The other day my attention was arrested by a black-looking patch in my garden, and on close examination I soon discovered all the symptoms so much complained of, and which seem to identify it with this almost universal disaster; and which I must, at once, pronounce to be neither more nor less than mildew. I may of course be wrong in my assumption: this, time must prove; but mildew in general has such distinct features, that long experience in such matters can hardly be mistaken. I feel astonished (assuming, for the moment, that I am right in the opinion) that this had not been discovered before. In the specimens which I have examined, in three distinct stages, the points all agree with those related from the southern parts of the country. In the first stage, the black spots look as though hot coals of small dimensions had been laid on given points.

Had it not been for the unambiguous character of the second stage, I should have fancied that it was a parasite belonging to the genus uredo.

The second stage, if I may so divide the matter, appears to be the rolling or curling up of the leaves all over the plant, exhibiting thereby the back of the leaves; and the whole plant, at this period, appears white with mildew.

This is soon succeeded by a general blackness and rottenness; the leaves are totally perished, the stem denuded, and the rot proceeding so rapidly that portions of the stem soon become a pulpy mass. I cut into some tubers this morning, which belonged to roots nearly in the third stage, and I found the end discolored in a considerable degree, more especially at that point where the string forms a junction with the potato; this is just what I had

expected. The potato plant, abounding so much in watery matter, appears to furnish a better subject than most plants for such rapid and astonishing effects of destructive fermentation, or decay of the whole system.

It is pretty clear to me, from the circumstance of its attacking the crop in the more southern parts of the island first, as also the earliest kinds in general, that this mildew requires a highly elaborated state of sap in the plant to facilitate its progress. Thus it is with the pea mildew. If the general elaborations of the plant move, through the influence of heat and light, at a greater rapidity than can be sufficiently supplied by the ascending current, the mildew spreads with great rapidity. I think it likely that the incessant rains, accompanied with such low temperature, have been quite sufficient to warrant the assumption that the fibrous action of the root has been much paralyzed. It is certain that the atmospheric conditions have not been as in ordinary summers. I take it for granted, that whatever arrests the secretions of the potato robs the tuber of a portion of accretive matter, and consequently of keeping as well as nutritious qualities.

R. ERRINGTON.

Oulton, Cheshire.

I have a piece of ground of about an acre and a half planted with potatoes. The soil is a fine hazel loam, and the field slopes towards the south. Most probably potatoes were never grown here before. I had the ground trenched 18 inches deep, in the autumn, and thrown up in hacks. The potatoes were planted in April, with more than a usual quantity of stable dung placed over the sets; so that they had every advantage of both drainage and manure. The plants were very promising until within the last three weeks, when an appearance of premature ripeness became visible. At this time—Monday, September 1st—the early Shaws have but little green remaining on their tops; the pink-eyed kidneys not much more; and the later kinds, though not withered, are as brown as they were last year at the end of October. I cannot find, in any case, that the stems have rotted, but they have turned black, and the foliage has quite disappeared. I dug up three rows of early Shaws this morning, and the produce has proved better than I expected. The quantity is very small, when the expensive mode of culture is considered; but the proportion of unsound tubers is not large. This unsoundness appears most on the potatoes nearest the surface, and presents a dirty brown color, which extends, in various degrees, into the structure of the tuber. The most remarkable circumstance is, that this discoloration is not associated with rottenness, since the part affected is as hard and as juicy as that which is sound. I observed, also, that one potato which had received a wound in the discolored part, was fast healing over, which, I presume, could not be the case if rottenness had commenced.

H. BURGESS.

The Bury, Luton, Beds.

A warm aspect and a well-drained soil seem to be no safeguard from the attacks of the potato plague, for I happen to know of an instance where ash-leaved kidneys, from the same seed, were planted on a dry, sunny bor-

der, in a private garden in this city, and on a cold, shady, damp border in the same garden; yet the potatoes in the warm and dry aspect are destroyed, while the others, under the shade and drip of the trees, have shown no symptoms at present of being injured. In the case mentioned, however, I cannot help suspecting that the latter will suffer by and by; the disease appearing to me to be in the nature of a fermentation or decomposition, which, when once induced, is encouraged and promoted by the presence of warmth. This view of the case also serves to explain the reason why the southern counties have been the first to suffer from this alarming desolation, and why the northern parts of the country may look out for its appearance amongst their crops before many days.

W. MARSHALL.

ELY, CAMBRIDGESHIRE, *September* 4.

I cannot agree with you in attributing the disease which affects the potato crop to excessive moisture. In the first place, is it a fact that the earth has been saturated with moisture to an unusual degree? Taking the deficiency of moisture during last year, I imagine not. But with respect to the potato crop, as far as I can perceive, there is not the slightest difference between those grown in light and heavy soil. In the neighborhood of this place there are acres on the light ferruginous sand, on the edge of the cliffs, and consequently thoroughly drained, on which there is not at this moment a plant that is not infected. What the cause may be, I do not pretend to say; but I do not think it can be traced to the excessive moisture of the summer. Had this been the cause, would not the decay have been more gradual? Would the destruction of the plant have been so very rapid? It is not merely wet that has done this mischief; it is the combination of cold and wet, acting upon very tender tissue. About that we entertain no doubt. We inquired as to drainage, rather than asserted anything about it, as you will perceive if *our* remarks are again perused.

W. E. H. SANDOUN.

ISLE OF WIGHT.

In the description given by Dr. Salter I have nothing to add, as I consider it very correct; but I confess that my observations differ from that gentleman as to the part in which the disease first takes its origin. He thinks it a kind of blight, beginning in the leaves and stems, extending downwards, and finally affecting the tuber. I confess my inability to explain satisfactorily what the real nature of this disease may be.

Dr. S. seems to think that we must trust the microscopical observations to discover a parasite on the plant. I am not aware that the disease which, when occurring in the animal world, is termed gangrene, or mortification, can be correctly applied to the vegetable kingdom, otherwise I should consider these brown spots to be incipient mortification, and that, as the effect of this condition, the death of the leaves and stem follows. A circumstance, accidentally discovered, seems to support this view. Previous to the appearance of this disease in any of the potatoes in this neighborhood, I was using at table some ash-leaved kidneys, of excellent quality, and so ripe that from natural decay the haulm was withered. A small quantity

of them, intended for seed, were left, and in a few days more, upon digging them up, great was my disappointment in finding them all more or less affected with this disease. Now, in this case there was not any portion of the plant above ground which could be at all affected by blight, or any other state of the atmosphere.

I am, therefore, disposed to suggest whether the disease is not one primarily affecting the tuber, and probably the effect of continued wet and cold, together with an absence of solar heat and light, whereby the chemical changes necessary for the formation of starch, albumen, and other inorganic products, have not been produced in the proportions necessary for assimilation. Chemical analyses of the tubers, thus affected, can alone prove how far this view may be a correct one.

* * *, M. D.

Eastbourne.

From the Gardeners' Chronicle of 13th September.

Having examined the tubers infected with the prevailing disease, I have scarcely a doubt left upon my mind that it is that moist ulceration (*gangrena saniosa*) to which all bulbs and tubers are liable, if exposed to ungenial circumstances at the time when their ripening processes should commence. At such time they require increased degrees of heat and dryness, and if subjected to the opposite extremes, as the potato has been this year, they for the most part ulcerate and decay. Take the tulip and hyacinth for examples. In confirmation or refutation of this opinion, I have instituted researches, which I hope to conclude in time for publication in the *Gardeners' Almanack* in November next; but they have extended sufficiently already to remove almost every doubt from my mind. If the July and August of next year are dry and warm, I do not hesitate to prophecy that there will be no potato murrain, and I think no preventive measures necessary beyond avoiding planting on plats of ground which have borne infected potatoes this year.

G. W. JOHNSON.

I learn, by letters from several foreign friends, that the disease which now affects the potato crops in the channel islands, and in several parts of England, is universal in Belgium, and almost all through France; and as Professor Morren, of the University of Liege, has described the malady, and the remedy to be immediately applied, I have seized the first moment of leisure to translate part of a letter which he has inserted in the *Independence*, of Brussels, for the benefit of those whom it may concern. The real cause of the disease is a mildew fungus, which scientific men class under the head of botrytis, but which the farmers will easily distinguish, and will name a spot, scorch, or burn. Some will attribute it to humidity, others to dry winds, to insects, &c. Nevertheless, it is of consequence to know the real cause of this phenomena; for the knowledge of it puts the farmers on the road to diminish or destroy, if it is possible, the evil. The professor has for several days followed the progress of the disease in several potato fields, and has come to the following results:

The malady decidedly commences by the upper part of the leaves; in

several instances he has seen the flowers and the seed-vessels first attacked. A part of the green tissue loses its color, and becomes yellow; the spots soon after become gray, and it is always on the under part of the leaf, or on the seed vessels, that the next day, or two days after the leaf has turned yellow, you perceive the formation of a white down. The microscope shows that this down is formed by a fungus which fructifies between the numerous hairs garnishing the under parts of the potato leaf. This fungus is extremely thin; but it fructifies immensely, and reproduces itself by millions. The professor, after having given a minute detail of the size, &c., of this fungus, concludes this part of his letter by saying: "Farmers will tell me that this is a very small body to cause such immense ravages; but I will answer, that the itch is not a malady less to be feared, because the acarus which causes it is a microscopic object. It is after the leaves have turned yellow, and the botrytis has made its appearance, that the stem is affected. Here and there the epidermis turns brown or black; and when you follow, with the use of the microscope, the infection, you soon perceive that it is by the skin that the stem is attacked. The morbid agent carries its action from the skin to the epidermis; and though you do not perceive fungus on this last part, it is not the less struck with death. For those who have a few notions of vegetable physiology, these effects are easily explained. The sap, modified in living juice, in vegetable blood, forms itself in the leaf, and descends through the skin in the stem and roots.

There the sap, being sickly, deadly, carries the poison from the leaf into the stem and kills it.

The fact is, that as soon as the black spots are seen on the stem, the leaves dry and die, and, struck with death by a poisonous mushroom, they fall, unfortunately, to deposite in the ground the germs of the poison. The infection soon descends into the potato, and, if the malady follows its natural course, it is soon affected with the gangrene; it turns brown or yellow, sometimes gray and dark, is soon spoiled, and the smell is so disagreeable that the animals refuse to eat of them. The disease being now known, the attention of agriculturists ought to be turned to diminish, as much as possible, the evil; because it is well known that all diseases which affect the corn crops, &c., once introduced into the country, remain and propaagate more and more. This year the epidemic seems to be universal; the germ is everywhere; and if a remedy is not immediately applied, the crops will be affected next year, and then it will become more difficult to extirpate the evil.

First, when the potato haulm is infected with the disease, mow it down, and immediately burn it. Second, act in the same way in potato fields that seem to have escaped the infection; for, though they may appear so to the eye, yet they may not have escaped the disease. Third, the potatoes diseased ought also to be burnt. Fourth, the seed for the next year ought to be steeped, like corn, &c., with lime, sulphate of copper, and common salt, diluted in water, in order to kill the fungus, if any, on the potato. Fifth, the potato fields ought to be next year as far off as possible from those of this year. Sixth, a mixture of lime, common salt, and sulphate of copper, to be powdered on the potato fields infected; this mixture having the power of destroying the poison left in the ground by the infected plants. For my part, I still hold to the opinion by me emitted—and I have seen nothing as yet to make me alter it—that the disease, in the first place, has taken its origin by the dampness and cold air which has been so prevalent during

the summer season. Since the warm weather has set in, (about three weeks,) the disease seems to have made but little progress; the tuber has been but partially affected, and, though swelling but little, seems to be sound and good. Nevertheless, the crop is a failure; averaging about half a crop.

RICHARD GIFFORD.

St. Peter's, Jersey.

Important to potato growers.—My attention has been given to the disease which has shown itself so extensively amongst growing potatoes. I find, in almost every instance, that the epidermis of the stalk, below the surface of the ground, is more or less in a state of decay, often disintegrated, and completely rotten. The leaves and branches accord with the state of that part below the ground.

The tuber beneath the outer skin is first spotted brown, (like a bruised apple;) these spots extend and penetrate towards the centre, quite changing the nature of the potato. Those near the surface are most injured. In some cases the lowest on the root are not at all affected, while the upper ones are useless. I should therefore expect that the longer the crop remains in the ground the greater the injury will be.

It seems, from the microscopic appearances, that the starch escapes injury for a long time after the skin and cellular parts are gone; and, as the whole of the nutritive powers of the potato reside in the starch, I should recommend that, wherever the disease has shown itself to any extent, the crop should be dug whether ripe or not, and the starch extracted by the following simple process: After washing the roots, let them be rasped fine and thrown into a large tub or other vessel; pour a considerable quantity of water, and well agitate and rub the pulp with the hands; all the starch or fecula will, from its great weight, fall to the bottom, while the skin and fibrous matter will be carried away by the water; wash the starch with one or two more waters, allowing it to fall after each washing; spread it upon cloths in a warm room, to dry. In this way about 20 pounds or 21 pounds will be obtained from every 100 pounds of potatoes; and it contains as much nourishment as the original roots. It will keep any length of time, and might be used with flour to make bread, pies, pudding, &c., as well as farinaceous spoon meal. This is much better than throwing away the diseased roots; and will furnish food for tens of thousands who might otherwise want it.

WILLIAM HERAPATH.

From the Gardeners' Chronicle and Agricultural Gazette, Sept. 20, 1845.

The attention of everybody is so absorbed by the *potato murrain*, that we should be wanting in our duty towards the public if we did not continue to advert to the melancholy subject. Not that we have much to add, either by way of advice or consolation; for the topics connected with the disease have all been already touched upon, more or less amply, by ourselves or our correspondents; and every week's experience satisfies us that there is little, if anything, to modify in the opinions we have ourselves already expressed.

The mischief is undoubtedly extensive to a most alarming degree. If we estimate the amount of loss at five-sixths, we shall hardly exceed the fact. In many places the crop is hardly worth digging; in others it is totally putrid; in many more, it seems to be spreading fast; and, as we mentioned last week, it has certainly broken out in Ireland.

"All my potatoes," says a correspondent near Dublin, "as well as those of the poor people here, are destroyed by murrain. Two days ago twelve acres were still safe; they are now gone."

Germany, Holland, and Belgium are in the same state as England. A dysentery, which has already appeared at Erfurt, is said by the *Gazette de Cologne*, to be traceable to the use of bad potatoes. The Belgium papers speak of cholera at Ghent, produced in the same way. Poland, according to the same journals, is so threatened by famine that the Prussian authorities, on the frontiers, have been obliged to take precautionary measures for keeping the starving population out of the Prussian territory; and finally, the authorities of some districts in France and Germany have either prohibited, or threatened to prohibit, the exportation of potatoes, lest there should be no seed for another year.

Such is the state of the case. It is useless now to speculate on the first cause of this murrain. Our original opinion was, we believe, correct—at least we have not at present seen anything to shake our confidence in it; and we find that, with the single exception of Professor Morren, the universal opinion among Belgian cultivators is the same as ours, except when meteors, electricity, and other unknown forces are appealed to. It is true that a minute fungus has made matters infinitely worse; but that is, we quite believe, a secondary cause.

The consideration of this part of the question may, however, be very well deferred. What we have now to look to is an immediate remedy for the evil.

From the very beginning we have pointed to dryness as the first means of arresting the progress of this disease. We even ventured to suggest kiln-drying, where means are at hand to employ it. We now learn from the *Belgium Moniteur* that a Dr. Varlez, of Brussels, has proved experimentally the efficacy of this process. The following is his account of his manner of proceeding:

"I caused an oven to be heated to the temperature of something less than 180° Fahrenheit. I placed in it diseased potatoes, both whole and cut, in order to be able to obtain an exact comparison between the parts baked and those not exposed to heat.

"After having been exposed to this temperature for a few minutes, a copious blackish matter oozed out of the potatoes, and they emitted a nauseous fetid smell. The corrupted matter came out, and when the potatoes were not too much diseased they became white again, and nothing remained of the rot except a slight brownish layer adhering to the skin, and easily removed by peeling. This layer is compact, and will permit nothing to pass through it into the interior. It loses, moreover, all power of injuring the sound parts that remain. As soon as potatoes are *quite dry* on the surface they may be removed from the oven. I found from 18 to 22 minutes long enough, when the temperature was such as I have described."

We are unable to say how long potatoes thus treated may be kept; but we imagine that there will be no difficulty on that head, if they are stored away in a perfectly dry place.

The question is, how far the cost will render the process of practical value.

Others recommend a steep of some kind as a means of stopping the mischief. This, if it will produce the effect, is the simplest process; but we are not aware of any positive result having been obtained by it. For ourselves, we have no great expectation of advantage from it. The mould fungus, which is now working so much havoc upon a debilitated constitution, buries its spawn in the tubers, far, we fear, beyond the reach of steeps; and, as to its seeds, why, they are finer than the motes in a sunbeam, and will insinuate themselves everywhere. We shall, however, be much obliged to any one who has tried any of the plans that have been proposed, for some account of the result. Mr. Prideaux has recommended chloride of lime and salt. Professor Morren also directs attention to the importance of salt as a means of repelling the disease. He recommends the tubers to be plunged in a steep composed of 54 lbs. of lime, $\frac{1}{4}$ lb. sulphate of copper, 7 lbs. of salt, and about 25 gallons of water. But, if the potatoes are to be eaten, the sulphate of copper must be left out; in fact, he recommends the steep for seed-potatoes only. There is one circumstance connected with the supposed action of salt, that deserves to be mentioned. In another column will be found a letter from a known correspondent, signing himself "Ambulator," who speaks of the healthy state of the potato crops on the coast of Somersetshire, although the murrain has committed its usual havoc beyond the reach of the sea influence. We also read in a Belgian newspaper the following statement:

"A person who has been travelling through Belgium, and especially the two Flanders, has remarked that on the coast, as far as the air is impregnated with saline particles, the potatoes are sound and perfectly healthy; but elsewhere, more inland, the epidemic is raging, and the potatoes become more and more rotten every day."

Are these coincidences, or do they indicate any protecting influence on the part of salt? The question is worth consideration. Has any one used salt in planting potatoes? and, if so, with what effect?

We find, however, that public opinion is turned more to the extraction and preservation of the *flour* which lies in the potato, and which constitutes an important part of its nutritive quality, than to any processes for saving the tubers by heat or steeps, the first of which is expensive and the last uncertain. It is a fact, that in spite of the ravages of the mould fungus, or the progress of putrefaction, the internal flour is as yet uninjured, and that it is practicable to extract it by very simple and cheap processes. This course is recommended by the members of the Hadleigh Farmers' Club, as will be seen from their resolutions, printed in another column; and we have received both from Mr. Berkley and Professor Henslow excellent samples of fine potato flour, extracted from the decayed potatoes. The latter gentleman found, that while half a bushel of sound potatoes yielded 4 lbs. 10 ounces of flour, the same quantity of diseased and decaying tubers furnished 3 lbs. 1 ounce. We have also received from a farmer at Hadleigh some good bread made by a laborer's wife from gleaned corn, and rather more than half potato flour, roughly prepared from very bad potatoes, and some sponge cake, worthy of Gunter, made exclusively of such flour, by Mrs. Patterson, the mistress of Hadleigh workhouse. In fact, the laborers' wives in Suffolk are setting in good earnest about the extraction of flour.

This being so, we think it important to direct particular attention to this

practical point; and, in connexion with it, we print the following valuable observations of Mr. Edward Solly, who is directing his attention to the chemical facts connected with the murrain:

Attention is now generally being drawn to the manufacture of potato flour, with a view to save some portion, at least, of the useful matter of the crop, instead of losing the whole, which appears to be the inevitable result if those tubers which are affected with the rot are left in the ground to ripen, or even stored up with others which are sound. The putrid matter which has been formed in certain parts of the plant, chiefly in the underground stem and roots, having been circulated through all parts of the plant, has induced decay or putrescence sometimes in the stem, sometimes in the leaves, and sometimes in the tubers. The putrid matter, or *ferment*, as it may be termed, contains nitrogen: it is, in fact, the gluten and albumen of the plant in a state of decomposition; and wherever it has caused decay, it has done so by causing the gluten and albumen of that part of the plant to enter into a similar state of decomposition. The next substance which begins to change is the cellular tissue, which, under the influence of the putrid azotised matter, putrifies also; and lastly, the granules of flour undergo the same change. It is almost impossible to arrest this effect in the tubers; for, when once commenced, it proceeds rapidly and with increased power, not only causing the whole of the tuber itself to decay, but also spreading to the surounding ones, the putrefying juice being fully able to develope putrescence in sound tubers.

The value of potatoes as food depends on the flour and azotised matter which they contain: in the diseased tubers, the latter is already destroyed; the former, however, remains sound, and therefore, by proper means, may be separated from the other substances, which are already destroyed, as constituents of food.

Water is essential to this species of decay, which would not proceed so rapidly if the potatoes of this year did not contain an unusually large proportion of water; hence the decay may be checked, or altogether arrested, by drying the tubers: this prevents the further spread of putrefaction, but it does not at all remedy the mischief already done.

The best plan, at present, appears to be that of separating the flour from the fibre, &c., of the diseased tubers. Those potatoes the haulm of which is already dead should be taken up at once, and partially dried by exposure to the air; this will check the progress of decay, and not interfere with the subsequent extraction of the flour. The following is a brief outline of the process requisite for this purpose:

"The tubers must be washed, and then grated or reduced to a pulp. Machines for this purpose may be obtained from agricultural machine makers, which will save a good deal of time when any quantity of potatoes is to be operated upon.

"The pulp, as it falls from the grater, should be collected in a canvass bag, as then the juice, which contains the greater part of the azotised matter, will drain away from the flour and fibrous portion of the tuber. The pulp must then be washed: this may be done on a sieve, or in a coarse canvas bag; the pulp being well stirred, whilst a small stream of water is suffered to run through it into a tub or other convenient vessel placed beneath.

"The water comes through milky, carrying with it the flour, and leaving in the sieve or bag the fibrous matter of the tubers, which may probably

be used with advantage in feeding pigs; but, as this is a matter perhaps open to doubt, it should be given with caution at first. The floury water, after standing about ten minutes, is to be poured off, when there will be found at the bottom of the vessel in which it stood a quantity of impure flour; this must be washed by stirring it up again with a quantity of fresh water, and then allowed to settle; the lower part of the flour will then be found to be pure and white, whilst the upper part is dark colored, and contains a good deal of decayed fibre; this should be separated from the clean flour, which is to be drained and placed to dry in a warm room, but not dried by artificial application to fire, which, if incautiously used, would be very likely to spoil it by converting it into gum. By this process, good flour may be obtained from potatoes which are brown and perfectly unfit for any other use; but as it is difficult to separate the decayed fibre from the flour in these tubers, it will be as well to separate as much as possible those which are quite rotten from those which are but slightly tainted, before grating.

"The quantity of flour in different kinds of potatoes varies considerably: on an average, a cwt. yields about 18 pounds of good starch; but some kinds yield considerably less. The quantity of flour in potatoes this year appears rather less than usual; but this is occasioned by their containing, for the most part, rather more than the usual proportion of water. The average proportion of water in good potatoes is about 80 pounds per cwt.

"The great advantages of proceeding thus with the diseased potatoes are, that, in the first place, the process is certain to succeed; and, in the second, that it costs nothing beyond a little labor of women and children, and such an apparatus as every cottager must have, except a bread rasp; and for that an old coarse file, or even a brickbat, or any thing else having a rough and hard substance, may be substituted; or the potatoes may be crushed by a heavy instrument. The arm of an old shirt, or the leg of a pair of worn out canvas trowsers, or a piece of an old flannel petticoat, will make strainers, fine or coarse, according to what is wanted, and no fuel is required to dry the material. All that the laborers have to attend to is not to allow the water and starch to stand for more than ten minutes at a time. It is true that all the azotised matter will thus be lost, but what is saved will have considerable value; and there is no sort of difficulty in the extraction of the flour, which, where cottagers are concerned, will be best effected by the first of the Hadleigh processes.

"There is an additional point on which a word of advice might be given. Professor Morren recommends that the haulm should be removed and burnt, whenever it is quite withered. The practice of cutting it off and raking it in heaps has been followed by many persons from the first appearance of the disease, and, as we have before stated, there may be some advantage in doing so. This, at least, is certain—that no advantage is gained by leaving decayed haulm on the field. We do not, however, attach much importance to the burning; it can do no harm, and that is all.

"Nor would we advise the haulm to be removed unless it is very bad; because, as long as it is green and healthy, it has a daily tendency to ripen the tubers, and thus to keep off the evil. If, however, the leaves are yellow, we should take up the crop."

The above was all in type, when we received the following very important communication from the Rev. Mr. Berkley:

"I have just received from Dr. Montagne specimens of a very curious

parasite, which occurs in the intercellular passages of potatoes during the process of germination, or just as it is completed. It was discovered in the course of some experiments by Dr. Rayer, chief physician of the Hospital de la Charite, at Paris, who has been paying great attention to the disease with which potatoes are now affected, and who purposes to publish an account of his observations, which I am assured are most interesting. Amongst other points, he finds that though the grains of fecula which are found in the cells of the diseased potatoes are not injured, they gradually diminish in number, as in the germinating sets, till in some cases all are completely absorbed. It will be important, then, to convert the diseased tubers into flour at as early a period as possible.

"Dr. Montagne considers the parasite above mentioned to belong to a new genus, allied to sepedonium and asterophora. He has given the little mould the name of artotrogus hydnosporus.

"Those who have had access to the late numbers of the Journal of the Institute, will find some interesting matter respecting the potato murrain."

The importance of this communication consists in its revealing the fact, that the flour itself disappears, though not undergoing decay. It is therefore of the first consequence that those who mean to operate upon their decaying crops should do so without a day's delay.—[*Editorial.*]

DISEASE IN POTATOES.

Notwithstanding the fineness of the weather, the potato blight is making rapid progress.

Patches which were perfectly green a week ago, are now blackened as if by frost. In every case I find the Botrytis infestans preceding the work of destruction. It appears while the leaves are yet green, or yellowish green, and the parts attached soon become brown and withered.

The appearances exhibited by some smooth ash-top potatoes in my garden convinces me that the spots upon the tubers arise from the attack of the mould, and that the mould is not an after organization. The spots form the most distinct concentric circles, disposed in one or sometimes two systems, exactly as in Oidium fructigenum, as figured by Ehrenberg, in his Mycetogenesis, and as it may be seen almost every autumn on fallen pears and apples. In re examining specimens in which there was no external appearance of mould, I found the spawn very evident in the diseased cells; but, as I before observed, the grains of starch sound and unaffected. Some of the cells contained little cubical colorless or brownish crystals, which I had not previously met with. If the infected tubers are shut up for a day in a tin box, the mould appears externally in little white patches, and soon fructifies.

The grains of starch being perfect, it was a matter of interest to ascertain whether the tubers would produce good potato flour. I accordingly chose six highly infected tubers, of a moderate size, some of which were strongly impregnated with spawn, and others partially decomposed, and I was pleased to find that they yielded about an ounce of flour, of which I send you a sample. You will perceive that it is *very slightly* discolored, but otherwise it is apparently of good quality; and I doubt not that, if

made on a large scale, very pure fecula might be obtained. My specimen, indeed, would have been of a purer white, but for a little accident.

M. J. B.

King's Cliff.

—

I remarked that whenever the crops were fully exposed to the influence of the sea breeze, especially on the sides of the hill sloping down to the shore, (facing north, northwest, and northeast,) they were altogether free from any appearance of the disease. An interesting question may arise from this, as to what the effect of a saline atmosphere may be in preventing the attacks of the fungus.

AMBULATOR.

—

Is it not probable that one of the causes of the disease arose from the poisonous matter belonging to the fungus mould being rapidly thrown back into the plant in the cold weather in the early part of June, following, as it did rapidly, the excessive heat of a few days previous? On the 12th, 13th, and 14th of June the thermometer, in the shade, marked 77°; in the sun, 95°; and on the 18th it was as low as 47°; the average temperature being 69° on the first three days, with bright sunshine, and no more than 57° on the 18th and 19th, with cloudy weather. All the potatoes examined present a similar appearance, and first begin to show symptoms of disease where the tuber is attached to the fibre; it thence gradually appears round the rim, through a vein, whence it rapidly spreads through the whole potato.

W. W. CHILDERS.

St. Hellier.

—

On my attention being first drawn to this disease, I took up a few potatoes which were just beginning to spot, and I must add, that in some places the blackness in the stem had just commenced; these looked, to all appearance, perfectly sound, but having been compelled to sort them over, (within a fortnight of their removal from the ground,) about 10 per cent. were found decayed, with the usual symptoms.

I have examined several of the neighboring fields, and the conclusion I have come to is, that, with regard to sorts, those of the grossest habit, and, with regard to land, that which is richest and oldest tilled, are the most unfortunate under the attacks of this pest.

On very poor soils, the disease would appear to merge itself finally into a sort of desiccation; the stems which on gross soils become pulpy, on weak and poor upland soils appear to wither and dry up.

R. ERRINGTON.

Oulton.

—

The appearance that the leaves of the potatoes in this neighborhood have lately assumed is so similar to that described in late numbers as the

first stage of the disease, that I am induced to send you specimens for inspection. I have not seen any instance, however, in which the tuber, or any considerable portion of the stalk, has decayed, though I have heard of some cases along the seacoast. Do you consider this to be the commencement of the same disease that prevails in the south of England? and, if so, can any thing be done to arrest it in its present stage? Would it be a good plan to cut off the stalks, or would it be preferable at once to dig the potatoes, though not yet ripe? My chief reason for hoping that it is not identical with the English disease is, that it could not have been caused in this county by cold and wet, having first appeared about a week ago, after a fortnight of dry and bright weather. As far as I can learn, it was first observed on the evening of the 8th instant, which was a very hot day, succeeding a slight hoar frost. [We fear the disease is our English murrain.]

WM. R. MEADS.

KINSALE.

From the Mark Lane Express.

I am convinced the cold and rainy weather experienced in July is the cause. Long before the haulm showed any observable sign of disease, the root was spotted. On examination, I found the stems damaged just below the surface of the soil, to that part attached to the old set. As the supply of sap was thus cut off, the tops soon afterwards began to show the effect: some died down very rapidly, others threw out fresh roots, that prolonged the existence of the stems, which still retain a greenish hue.

Some potatoes taken up in July for family use were so black that they were laid aside; the crown end was generally the worst. I have since frequently examined these potatoes, and from their present appearance I conceive that exposure to the atmosphere will stay the disease from sinking into the potatoes. These potatoes soon became pitted, the diseased parts fell in, and became dry and hard, and now peel off with the skin, showing a sound and uninjured remnant beneath. This circumstance, I think, proves excess of moisture, aided by the cold state of the atmosphere, which prevented the usual exhalations, to be the cause of the disease.

G. S. C. BURROWS.

STOKE HOLY CROSS, *Sept.* 9.

In every case I have found the same result. The potatoes exposed to the air in any part are tainted more or less by the rot on their surface. Those only one inch under ground are perfectly safe. The haulm of all is withered, except in certain spots under trees, and there it is still erect, and the end leaves still green, although it generally withers first in those spots in ordinary seasons.

I should here observe that my garden is on the north base of a hill 600 feet high; that it is so much shaded by trees as to have, in the height of summer, not much sun, and in the early spring the sun scarcely touches it, rising very little above the hill. Yet, at such seasons, when my neighbors on more open spots (even on the south side of the hill) complain of sharp night frosts, my garden scarcely, if at all, suffers; and my crops are generally as good and very nearly as forward as theirs.

From these premises, I come to the conclusion that the cause of the mischief to the potatoes is the cold, and nothing but the cold, which we had in July, after great heats.

The potato (a native of Chili) is always sensitive of cold—the slightest frost in spring cutting off all above ground; and I conclude that when the tuber is in a state of rapid growth during the heats of July, a sudden and great diminution of temperature, without amounting actually to frost, is enough to damage its surface.

We see the effect here, in the corruption of such tubers as have grown in contact with the outward air, as well as in the general withering of the haulm, while that which is protected by trees overhanging is preserved, and there seems to be hardly a reasonable doubt that the cold alone is the cause.

Of course, in districts exposed to the colds, as potato grounds usually are, the effect will be much more severe; and the failures of the crop in Belgium, (a flat, open country,) about which there has been so much learned speculation, seem to fall in with the theory.

I find that my neighbors who have suffered most plant as shallow as possible. I have my potatoes planted at six inches depth, whenever I can overlook the gardener, and oblige him to comply with my whim. Your constant reader,

E. V.

Bath, *Sept.* 11.

To the Editor of the Gloucestershire Chronicle:

The disease apparently attacks the plant in the fibrillæ of the roots, and where the root passes into the tuber or solid bulb of the potato. An interruption having taken place between the supply and demand of the living plant, by the decay of the root and its fibrillæ, its stalk quickly drops and withers, in proportion to the progress of the malady. The thin outer coat of the potato may now be perceived roughened and thickened in one or more patches; and these, when cut through, show that the internal structure of the tuber is altered—the change commencing immediately beneath the cuticle or outer skin; the pulp is changed to a rusty brown color, like a bruised apple, in thickness varying with the intensity and duration of the disease; eventually the structure of the whole potato is converted into a reddish-brown, half-rotten looking mass.

When slices of the altered structure were examined through a microscope, many of the cells containing the farina or starch were thickened, enlarged, and emptied apparently of their contents, the appearance differing in many respects from the natural formation of the healthy tuber. Here and there could be seen small transparent globules: some of them, apparently becoming more opaque, and a few surrounded with opaque reddish-colored fibres, might be considered to belong to some species of minute fungus—perhaps the torula, a species of which is found in the products of fermented liquors. This disease, whether produced by parasitic fungi, or by change of structure, induced by atmospheric vicissitudes, rapidly destroys the potato affected with it, rendering it at once innutritious and unwholesome—the farina of the pulp being converted into sugar and the diseased fungoid-looking substance.

Having, as far as opportunity and leisure permitted, attempted to describe

the disease, I will now suggest the remedy: Chloride of lime, or chlorinated lime, is a well known disinfecting and anti-putrescent agent; it will prevent insects and parasitic fungi attacking seeds and plants; this remedy is a safe one, and free from poisonous effects, not being injurious to vegetable growth when properly diluted and judiciously applied. Therefore, to this active agent would I advise all those who wish either to prevent the ravages of the disease, or to check it before thoroughly developed in the plant, to have immediate recourse. The mode of applying it may be as follows: Mix one ounce of the powder of chloride lime with a gallon of water, and well sprinkle the solution over the rows of the potato crops. I would also recommend the same solution to be sprinkled over the recently dug potatoes, but they must afterwards be dried before laying them up in store. A very small portion of the powdered chloride lime might be mixed with the saup or gravel laid over the floor of the potato bury or cellar.

I beg leave to remain your obedient servant,

THOS. HICKES, *M. R. C. S.*

GLOUCESTER, *Sept.* 11, 1845.

P. S.—Since writing the above, I have seen in this day's *Times* a letter from W. Herapath, esq., the celebrated professor of chemistry at Bristol, whose views in a great measure coincide with mine: he wisely advises the potato crop to be immediately gathered, the diseased tubers grated and prepared by washing in water, and the farina of the pulp, or potato starch, which is nearly as nutritious as arrow-root, may then be preserved for future use.

THE POTATO DISEASE, AND ITS ANTIDOTE.

To the Editor of the Mark Lane Express:

The manufacture of farina by the farmers has been recommended at present only as a "dernier resort;" but I would wish to show that it is a measure which should be adopted by all farmers who grow potatoes—not alone as a protection from the rot of the present year, but from the loss which always ensues from storing large quantities.

In addition to the general amount of loss by decay, another deterioration takes place, not generally known—namely, *loss by vegetation.* From the moment that that commences in the potato, the quantity of nutritive matter declines; so much so, that I have found the produce of a given quantity of potatoes, from the same crop, vary from 15 to 20 per cent. within a month in spring; in fact, the potato, which, if manufactured during winter, will yield one-fifth of pure farina, (possessing every property of the best arrow-root,) will not give more than a *tenth* if held over till May or June; and the loss is equal to the farmer, whether he consumes or sells, *for, in proportion as the vegetation proceeds, weight diminishes.*

It must be evident, therefore, that inasmuch as the true nutriment of the potato exists in the farinaceous particles, their preservation at the period they are most abundant should be the object of the farmer; the more particularly, as, thus preserved, farina becomes food for all classes of animals.

For man, its benefits are most varied. Used, in the proportion of a fifth or fourth, with wheaten flour, it produces a much better and more wholesome bread than from wheat alone. For pastry, in the same or greater pro-

portions, it is infinitely preferable; and in all cases where flour is used for culinary purposes, it is in every way better and more nutritious. When once properly dried, it possesses the invaluable property of absolute resistance to damp or mould; and it has been proved that sea biscuit, made in the proportions named, returned, after a voyage of three years in the tropics, perfectly free from weevil. In short, for household use it possesses the most singular advantages, (amongst others, being really a better *starch* than wheaten,) and is sold now in large quantities, under the designation of "*patent soluble starch.*"

For cattle (particularly for rearing calves) its value is also very great; and, mixed with any coarse stuffs, it gives the most abundant advantages. In addition, the pulp or fibre of the potato, which should also be saved and dried as well as the farina, is an admirable food for pigs; resembling more, in its effects, *barley* feeding than any thing else, and producing a very white meat, with a transparent fat.

But, before I conclude what, as I fear, is already too long a letter, I must add, that even the smallest potato in the crop will yield its quota of farina, while, if sold, it brings but a third, perhaps, in price; and thus another advantage accrues, by enabling all inferior sized potatoes to be manufactured, while only the best ones are kept for household use.

I am, sir, your most obedient servant,

JASPER W. ROGERS.

DUBLIN, *Sept.* 26.

From the Mark Lane Express, September 22.

THE POTATO CROP.

At a meeting of the Hadleigh Farmers' Club, on Friday, September 13, the lamentable failure of the potato crop formed the principal subject of discussion. In the hope of allaying the alarm which prevails in the neighborhood respecting the use of potatoes that have become partially injured, and also of suggesting a method by which a large amount of wholesome food may be saved from such as would otherwise be thrown away or given to pigs, it was resolved that a statement should be circulated, expressing the opinions of the club on these subjects.

I. It appears to be certain, that the failure is entirely owing to the season having been unsuited to fully perfecting the tubers of most of the varieties of the potato.

II. Wherever the leaves and stems are dead, it is advisable to dig up the crop as speedily as possible, and to select the best tubers (to be kept apart from the rest) for seed potatoes. It is probable there will be a great scarcity, when sets will be wanted, unless precautions are pretty generally adopted for saving the best.

III. The potatoes thus separated for sets should be preserved with more care than usual. They should be kept as dry as possible, and examined at intervals to see whether any of them are beginning to decay, and all such should be immediately removed.

IV. The spotted and decaying potatoes should be carefully picked out from among such as are to be preserved in store for winter and spring use.

V. As there is great danger from a single decaying potato being left in contact with others in the same heap, lest it should tend to rot all around it,

care must be taken to stack the store potatoes in layers, with sand or dry earth between them, and so that each potato may be prevented from touching its neighbors. A trench might be advantageously dug around the store; and if the whole were thatched, it would tend to keep them very dry. It will be advisable to delay the operation of clamping as long as possible, to allow the potatoes to dry the more thoroughly.

VI. The progress of decay in the spotted potatoes may be stopped (at least for some time) by exposing them in dry situations to the light, but their decay will proceed if they are placed in the dark, or on moist ground.

VII. If the decaying parts are pared off, or cut out, the rest of the potato is perfectly wholesome. Many idle rumours have prevailed to the contrary, which are unworthy of credit.

VIII. If the decaying potatoes have not passed to a state of putridity, they may be safely given to pigs; but they would be improved by being scalded, with the addition of a little salt.

IX. It seems to be a providential arrangement that, as yet, the really nutritive portion of the potato is very little injured, even in those tubers which have become partially decayed, and appear to be wholly unfit for food. The nutritious portion of the potato consists of delicate white grains of starch like matter, which are enclosed in little cells. When the cells are broken, the grains fall out, and, collecting together, form a beautifully white flour. It is very easy to separate this flour from the rest of the substance of the potato; and if a few persons in different villages would undertake to make the method generally known among the poor, a vast amount of wholesome food may yet be secured to them, which otherwise they will suffer to perish. From an experiment that has been tried during the past week, it appears that where 12 lbs. of flour can be extracted from a bushel of sound potatoes, 8 lbs. can be procured from such as have become so far decayed as to be useless as an article of food.

X. To obtain the flour separate from the decaying cells, the potato should be first very thoroughly washed, so that not a particle of dirt remains upon them. They should then be finely grated with a bread grater into a tub of water, and the pulp well stirred about to separate the particles of starch, as much as possible, from their cells. The whole should then be left to settle, and the heavier particles of starch will soon fall to the bottom, while the lighter skin and cells will continue floating in the water, and may be poured off with it. The mass of flour formed by the settling of the particles should be washed two or three times more, by pouring water upon it and stirring it about, and again leaving it to settle as before. After the flour is considered to be sufficiently washed, it must be spread upon a cloth placed on a board in the sun, or in a warm room, to dry, or it may be dried in the oven after the bread has been removed. It may then be kept for any length of time, and, when wanted, used like wheat flour for making puddings, &c. This process will be sufficient for common purposes; but a more perfect method may be described, by which the potato flour can be procured in its purest state, in which it is frequently sold for arrow-root, and by a variety of other names, as a delicate food for weak digestions, for children, and for the sick.

XI. The more perfect process for obtaining the flour in the form of "British arrow-root," is as follows:

1. Thoroughly wash the potatoes.
2. Peel away the skin, without cutting off much.

3. Grate the peeled potatoes finely into a pulp.

4. Place the pulp on a hair sieve, pour water over it, stirring it about well, till the water ceases to pass through with a milky appearance.

5. The pulp left on the sieve may be thrown away, and the milky water put aside to settle.

6. When the particles of starch have all settled, the water should be poured off, and fresh water added—the whole stirred up afresh and allowed to settle again.

7. These washings may be repeated four or five times, when the starch will have assumed the character of arrow-root, and will have become white as snow, while the water will now be perfectly clear.

8. The prepared flour must be thoroughly dried, and may be kept for any length of time in jars or casks.

XII. When a dish of potatoes is about to be obtained from the inside parts of such as are only partially decayed, instead of peeling them the decayed parts may be grated, and whatever starch can be extracted from these parts might be added to the boiled potatoes. Thus very little will be lost of the whole amount of nourishment which the potatoes would have contained if they had been quite sound. In many cases it may be more convenient to keep such gratings for three or four days, till enough has been collected to make it better worth while to complete the process.

XIII. In times of scarcity, it may be useful for persons to be made aware of the fact that excellent starch-like arrow-root may be procured from certain wild plants. In the Isle of Portland, some of the poor are in the habit of preparing it from the tubers of the plant commonly called "lords and ladies," (*arum maculatum.*) The tubers are well washed and grated, and the pulp treated like that of the potato. The process gets rid of an acrid juice with which the fresh tuber abounds. This sort of arrow-root is sold in the neighborhood of Weymouth for about 8*d.* the pound.

XIV. It was suggested that local companies or societies might be formed to buy up the decaying potatoes, and to employ some of the poor to prepare the starch, which could be sold at little or no loss. It is the practice in Scotland, when the store potatoes are found to be frozen, to extract the starch from them in the manner described.

From the Bristol Mercury, September 20.

THE POTATO DISEASE.

The following correspondence has just taken place between Lord Portman, President of the Royal Agricultural Society, and William Herapath, esquire, the eminent analytical chemist of this city, in reference to seed potatoes for 1846. His lordship, in a subsequent letter, requests that the correspondence may be made public, and it has been handed to us by Mr. Herapath for that purpose. The subject is of vital importance, and is worthy of the deepest attention.

"Bryanston, *September* 13, 1845.

"Sir: I observe in the newspapers that you have directed your attention to the potato disease, and have advised as to the use of the starch, &c. As I am specially bound, during this year of my holding the office of President of the Royal Agricultural Society of England, to promote inquiry and

to notify observations on subjects relative to the produce of the soil, I trouble you with this letter, and ask if any method has occurred to you by which the potato may be preserved for the planting of 1846? I have found that potatoes apparently sound and free from the disease, though in a field or garden which has been partially diseased, have, after being stored away, shown signs of the disease, and have rotted off; and I fear that the greatest quantity of the potatoes will thus perish, and so continue the distress of the poor into another season. I have directed some potatoes to be stored in slacked lime, in the hope that it may preserve them, but have, of course, yet had no time to judge of the effect. I therefore ask for your opinion, as one of our most eminent chemists, upon this point, and would ask leave to make known your reply, if you are able to offer an opinion sufficiently explicit to be useful.

"I remain your obedient servant,
"PORTMAN.

"Wm. Herapath, Esq."

"Bristol, *September* 17, 1845.

"My Lord: In reply to your letter of the 13th instant, I must say that I do not think it would be either safe or prudent to depend upon the infected potatoes of the present season as seed for the next year; as, in all instances, I have found the diseased parts to extend when the potatoes are kept in a damp situation. I should therefore expect that if any diseased seed was kept so dry as not to rot before setting time, yet, upon being planted and left in the damp soil, the rotting process would then begin, and the hopes of the husbandman be disappointed. I have no doubt that some potatoes, apparently sound, have (as stated by your lordship) been found to be affected after stowing away; but I do not consider this to have been an origination of it, but merely that which was unnoticed when dug has become apparent after storing. When a potato is first affected, the diseased parts are scarcely visible; but upon keeping it in a dry place, the spots soon become dark, and consequently more apparent, but the spots do not extend; if, however, the tuber has been kept in a damp place, the spots not only extend rapidly over the surface, but penetrate into the interior, and in a short time it will be completely rotten. As far as the slacked lime, which you have used in your potato stores, has a tendency to prevent the tubers from touching each other, or, by its power of absorbing water, of keeping them dry, it will answer a good end; but it must not be expected to have any chemical effect upon the diseased parts or their juices. Anything which, like dry sawdust or sand, would prevent contact, would prevent the propagation from one tuber to another; and any substance capable of absorbing the moisture of the air in which the potato is stored, would prevent the extension of the disease in each diseased root. Our best microscopists and cryptogamists are divided in opinion as to whether the cause of the calamity is a fungus or not. After all the examination I have given to the subject, and a careful review of all the evidence brought before me on the two sides, I believe that it is; and I am daily confirmed in the opinion originally expressed, that the only advantageous way of treating the diseased potatoes is to obtain from them, by rasping and washing, the starch which they contain, by which process all their nutriment can be retained; and if it is well dried, it will keep for any

length of time. The operations can be performed in the cottage or manufactory alike, as no apparatus beyond a tin rasp, (a nutmeg grater) a tub, and clean water, are required; and I have ascertained that however far the disease might have extended, even if the root is rotten, yet the starch can be separated, and in a state fit to be eaten, if it shall be well washed, as all the bad parts come away with the water, while the great weight of the starch carries it to the bottom of the vessel. If it is required that the fecula should have all the qualities of the best foreign arrow root, it is only necessary to wash it last in water containing a little chlorine, when it has unrivalled color and quality; and this I can speak of practically, having made many tons of the article.

"I will only add, that an opinion has been circulated that the disease is owing to the introduction of guano as a manure; this I feel no hesitation in contradicting, as I have seen it in situations where no guano has been used, and where every other variety of manure has been resorted to.

"I am your lordship's most obedient servant,

"WILLIAM HERAPATH.

"To Lord Portman, *President of the Agricultural Society.*"

From the Mark Lane Express, Sept. 29.

STORING AND PRESERVING POTATOES.

To the Editor of the Exeter Flying-Post:

Sir: As the hope of saving the important potato crop precludes waiting the result of our experiments, I have again to offer suggestions for others also to consider, correct, or improve.

The failure of the last, where the added moisture counteracted the benefit of the salts, has been a guide to my present experiments, which have not yet time to test their efficacy. It must, however, have fallen under the observation of others, that, of two parcels of the same potatoes, whilst one, heaped together, will putrefy, the other, spread out on a dry floor, will make no progress in decay, but rather lose their offensive smell. Hence, without staying at present to discuss the *cause* of the rot, drying appears to be one of the readiest means of checking it; and, accordingly, kiln and oven-drying have been recommended, both of which appear to me quite inadequate to the great quantity of the subject, with its large proportion of juice.

Before suggesting another method, let me ask whether others have also observed three varieties of the rot, either different degrees or belonging to different kinds of potato?

1. The tuber not much discolored inside or out, but having a pungent odor when cut, like putrid horse-radish, and decaying quickly; this chiefly in white potatoes.

2. Brown spots or patches more or less throughout the tuber, with little offensive smell, and much slower in progress than the first; this chiefly in red potatoes.

3. Coating, limited to the compact outside layer, the inner side of which is often marked by a distinct brown outline, the heart remaining sound and sweet; this only in reds.

This division is not taken as the basis of the classification below, being drawn from local and limited observation; but, if found coincident with the appearances in other places, may assist in the selection,

Dr. Lindley, (*Gardeners' Chronicle*, August 30,) whilst recommending kiln-drying to such as have opportunity, seems to feel its inadequacy generally, and suggests pitting in dry earth, so as to prevent contact and communication by perspiration. But can we not, by using *fire*-dried earth, which will absorb much moisture from the potato, effect the double purpose of drying and separation? With this view, the potatoes may be divided into three classes or conditions.

1. Apparently sound: to be pitted in fire-dried earth, entire.

2. Infected, but not hopelessly decaying: to be cut and pitted as the first; with or without salt.

3. Putrescent, unfit for use or keeping: to be ground into starch, without delay.

A brief explanation of each of these three methods may be sufficient for our present purpose.

1. Apparently sound. However impracticable it may be to find oven or kiln room for our potato crop, there is no great difficulty in fire-drying any requisite quantity of earth; which may be done in heaps, in the field, in some of the methods practised for clay or marl burning, only using small coke, "brise," or cinders; as the ashes of wood, or soot from coal, might excite vegetative action, and thus prevent the good keeping of the potatoes.

Air-dried earth contains much moisture, which may be driven off by a heat a little above boiling water, leaving the earth very greedy for damp, which it will suck from the air, or from any juicy substance in contact with it; but if made red hot, it loses much of this attraction for moisture, and should therefore be rather dried than burnt. The sooner it is pitted with the potatoes, after cooling, the better, that it may have the less time to draw moisture from the air. It should, however, be quite cold, because potatoes spread out in the sun are said to rot quickly. There should be earth enough to fill in between the potatoes, and keep them in separate layers; and it is almost superfluous to add that they should be pitted in very dry ground, and covered from the rain.

The poorer the earth in humus the less smell it will acquire in fire-drying; but sandy soil is very little absorbent.

2. Slightly infected. These may be cut in halves from stem to nose; when such as appear past hope may be turned over to the third class, for starch.

The less damaged may be pitted, with the dried earth, in separate pits from the sound ones; when the earth in contact with the cut sides will suck out the diseased sap.

It is a question whether the earth for these might not be mixed with some salt, (say one-sixth or one-eighth,) which would not only help to suck out the sap, but would more or less enter the substance of the potato, and probably contribute to its preservation. The salt might be tried in a pit or two only, at first; and extended in its use, afterward, if found to answer best, as the potatoes come to be taken out for sale or consumption.

These two methods can be regarded only as experimental, with a view to preserve the potatoes at the least loss and expense. The following is more costly and wasteful, but certain:

3. Those which are far gone, even half rotten and stinking, will still make good sweet potato starch, (see note) which will keep for years, and, with one-third flour, make excellent bread, puddings, or pastry.

For this purpose nothing more is required (as already stated in the pa-

pers) than a grater, a fine hair sieve, two or three pans, trays, or tubs, and plenty of clean water. The potatoes must be thoroughly washed, the very rotten parts cut out, and the clean part grated into the sieve. Here it must be continually stirred about, and watered with a watering pot, to wash the starch through the sieve, into a pan or tray, to settle.

While the starch is settling, the pulp remaining in the sieve may be pressed in a cider press or otherwise, and, if well squeezed, will keep a few weeks, sprinkled with salt and vinegar. It may be boiled for pig feeding; and as vinegar is the best preservative of vegetable substances, palliates the action of vegetable poisons, and has a particular tendency to fatten pigs, it is a very desirable addition. Where, however, vinegar is wanting, other acids may answer, as the muriatic or sulphuric, in very small quantities; perhaps even the apple pumice; or the potato pulp itself will often turn sour by standing open in cold water twenty-four to thirty-six hours.

When the starch is settled, the best and whitest will be at the bottom, covered with particles of peel and discolored fibre; and a little management is necessary in washing off the upper part, from vessel to vessel, and letting it settle repeatedly, to get as much of the clean white as possible from the colored. The last colored residue may be thrown back with the pulp. After several washings, the water may be poured away, and the white starch laid out on a cloth, upon some bricks or dry earth, to absorb the moisture, and then very gradually dried.

This is, however, a tiresome process, ill suited to the economy of a farm; the grating is slow, the repeated washings tedious, and the drying much in the way. It would be better done at the Union Workhouses, where the cleaned potatoes could be ground in a mill, figured and described in Parnell's Applied Chemistry, vol. ii, 133; and Ure's Dictionary of Arts, &c., p. 1166. This mill is not costly, and will grate two or three tons in twelve hours. There must be, of course, several sieves and watering pots, and a drying room is easily contrived in such an establishment.

Yours, &c.,
J. PRIDEAUX.

Note.—In the microscopic examination of a great number of potatoes, I have never found the starch damaged; it was either perfect and colorless, even when the cells and fibrous matter were quite brown, or if affected at all, it was completely dissolved, leaving the cells empty.

From the Brighton Gazette.

Various causes of the disease have been assigned, some ascribing it to the wet rot; but we cannot go away from our opinion, that it is in a great measure owing to the luxuriance of growth, induced by warm rains falling on the dry land after planting, and followed in June and July by hot, sunny weather, as it must be admitted that the ground has never been thoroughly saturated during the summer, although we have had much showery weather. The cause is ascribed by some to the tubers of last year having been allowed to get over ripe before they were dug up, and consequently unfit for planting. There is no doubt that over-ripe plants are more subject, in their growth, to the curl than the unripe ones; but if that were the cause of the general rot we have amongst them this year, both on the

Continent and in England, it is strange that the unaccountable disease has not shown itself generally before; for it is usual for farmers, in the south of England especially, to let their potatoes stand until the haulm dies before they take them up. The present summer is acknowledged not to have been so wet as the summer of 1843; and if so, why have we not seen the disease either in that year or in some former wet summer, when our potatoes have perished in places from the wet rot, but without showing the extraordinary symptoms and general decay of this year? It no doubt arises from natural causes connected with the weather, and we hope never again to see so serious a calamity, in the failure of this useful root.

From the Mark Lane Express.

POTATOES.

Sir John Maxwell Tilden has addressed the following communication to the editor of the *Gardeners' Chronicle:* "Having been particular in my examination of the plant, from the first appearance of the spot on the leaf, which attracted my attention in less than a week after its appearance, I feel confident that your explanation is quite correct, namely, that it is atmospherical and not terrestrial; or, in other words, it is caused by the want of due ventilation, evaporation being stopped by the damp and cloudy weather of July and August. Previously the plants grew with almost unexampled rapidity and luxuriance, so that the disease is more like apoplexy than any thing else. I found that when the disease first showed itself on the leaf, the tubers were sound to all appearance, but, when dug up for some time, some showed the plague-spot; but if the potatoes were forward enough to be dug up before the disease appeared on the leaf, they were still sound. The kinds I have examined are an early kidney, and an early round potato, having no particular name, and both having been grown on the spot for twelve years; and of the later sorts the Peach and the Red Rough are the only two I grow. These are but little affected, yet I find that every hill has one or more bad tubers. The diseased tubers of the early sorts are now shooting out in the ground where there is a sound eye in the root, and I have this day seen some with nearly half the tuber decayed, and from the other a shoot of two inches long, looking fresh and healthy. This has suggested to me the plan of endeavoring to save seed for next year by autumn planting; and I mean to proceed thus: Have all dug up as soon as I can, take out the sound ones, and leave those partially diseased on the ground to green, if they will, for about a week or ten days, and then to plant them as for a crop. Should they rot, nothing will be lost; for I consider they are more likely to rot above ground, and there will be time enough to plant again if seed can be procured; but I am convinced they will grow, as the very early sprouting of the diseased tuber (the healthy ones not having made the least shoot) shows that nature is taking her own course to preserve the plant. I shall not hesitate to plant in the same ground, but without fresh manure, as I do not wish to urge vegetation too fast, as I am quite convinced that the disease is only infectious by contact, and that it is not at all in the ground, but solely caused by the absence of sun, and excess of cold and damp."

From the Mark Lane Express.

After having read the many opinions given in your excellent journal, as to the malady and cure thereof, I have carefully watched the [potato] disease, and have come to the conclusion that the continued wet, *without sun*, is the whole and sole cause. I have also proved, beyond a doubt, that had we mown the haulm on its first visible appearance, we should have stopped the disease extending itself to the potato; that we should perhaps by that means have had our potatoes small and sound, instead of large and rotten. The above opinion I confirm, by having had worms in a field of wheat, and replaced the missing plants with potatoes, after which the plant of wheat so improved as almost to produce a crop among the potatoes; that in cutting the wheat about a month since, a quantity of the potato haulm was consequently cut or destroyed, and where that took place the plants have since been dry, and prove quite sound and good; since which I have had the whole of my potato haulm mown down, which should have been done a month sooner; but, " better late than never;" therefore I concur with your correspondent as to their being benefited by being harrowed.

A Kentish Farmer.

September 18, 1845.

To the Editor of the Times:

The real cause of the destructive changes at present taking place appears to be the unripeness of the tuber, and the consequent imperfection of elaboration of its juices. When examined with the microscope, the cells of the potato are found to be not more than half filled with starch-cells, many of which are incomplete, the remaining portion of the cell being occupied by water. Hence the actual condition of the potato may be stated as follows: 1st, deficiency of starch; 2d, imperfection in the tissue of the cell walls; and, 3d, excess of water; to which may possibly be added, imperfectly elaborated starch. As a consequence of the imperfection of the tissue of the cell walls, and its state of maceration in a superabundance of water, it falls speedily into decay, the change beginning at the surface and proceeding inwards, and being indicated by a brown discoloration of the cells. The starch cells, which are at first unaffected, are soon enclosed in the decayed cellular tissue, and, becoming involved in the decay, are thereby destroyed.

Taking this view of the state of the potato, two modes suggest themselves of preventing the loss which must necessarily result from the recurrence of the above described changes. The first is that recommended more than a week since in your journal by Mr. Herapath, viz: of separating the starch by reducing the potato to a state of pulp, and collecting the washed precipitate. When it is recollected that the starch embodies the whole of the nutritive part of the potato, the importance of this plan will at once be perceived. But, practically, there exists a great obstacle to the prosecution of the plan in the inconvenience of employing it on a small scale.

The second mode, that which I am now about to suggest, seems to me to be calculated to meet the exigencies of the case, at the same time that it is free from the objection stated above: it is, to dry the potatoes in an oven or kiln at a moderate temperature, and thus drive off the excess of water which they contain, the water being a chief agent in the decomposing process.

In preparing the potato for table the discolored parts should, of course,

be cut away; the potatoes should be boiled in two waters, and salt should be mingled with both.

I have the honor to be, sir, your obedient servant,

ERASMUS WILSON, F. R. S.

UPPER CHARLOTTE ST., *Fitzroy square, Sept.* 23.

To the Editor of the Dublin Evening Post:

I am indebted to a gentleman who resides in the neighborhood of Clontarf for the result of an experiment which he tried with perfect success. About three weeks ago, the disease having reached the neighborhood of Clontarf, my informant became alarmed for the safety of his potato gardens, and having seen in the *Evening Post* that the disease had its origin in the stalk, he resolved on removing the cause of communication to the potato, and without delay employed a great number of hands, and pulled up every stalk in the field. He is now digging out the potatoes, and never had finer in his life. The stalk cannot, at this late period of the season, yield further ripening sustenance to the potato; it might communicate the disease, and ought, on the latter account alone, to be removed. Not by the scythe, for the fibres would, as before, continue attached to the potato, and as much of the stem as would remain above the surface might be as pernicious as the entire stalk. The stalks ought to be, by the hand, one by one, carefully pulled up and removed from the field, lest, by heating in heaps in the first process of decomposition, the heat and effluvia might communicate with the potato near the surface, and perhaps diffuse the disease complained of, or some other equally destructive. The persons employed in the operation should be directed to place a foot each side of the stalk, by the compression of which it will come up freely, without disturbing the potato in the soil, in which it lies imbedded. W.

From the Mark Lane Express.

PEEBLESSHIRE.—From the general nature of the disease, there can be no doubt whatever but that it is produced from some general cause; and that, without hesitation, we attribute to the *cold, wet, ungenial season.* We find, in a field where a large proportion of the potatoes were earthed up with more than ordinary care, being some inches deeper in the furrow than the tubers were planted, which had the effect of preventing any excessive moisture remaining in the drills, that when the potatoes were lifted, so far as the unassisted eye could discover, they were perfectly free of any taint whatever, while in the other portion of the field, which had been less attended to, a large proportion of them was found diseased. We also find, by taking a potato of the *soundest* description, and allowing it to remain for two or three days amongst earth over-saturated with water, that the same disease is produced as that which is now so prevalent over all Scotland. A single drill in the field alluded to was planted with potatoes raised from the apple three or four years ago, by a knight of the shuttle, on the banks of the Ettrick, which were found, upon examination at lifting time, to be much more diseased than any of the other kinds we had planted. And others, too, we find from inquiry, who had tried the new varieties, have

met with a similar disappointment. In fact, until such time as we began to raise new varieties from the seed apples, such a thing as failure or disease was never once heard of; and to the result of this experiment we in no small degree attribute the deterioration of the *late* potatoes.

Fife.—The disease is still increasing; and great quantities, which seemed quite free from disease when lifted, have become quite *mouldy* and *rotten.* We regret we have been *so soon* able to report that several modes, adopted with a view of stopping the malady, have proved *fruitless.* Some were pitted very thinly, and ventilated with drain-tiles. The potatoes being quite dry when put in, have been found on the *decline.* Others, that were sprinkled over with lime, have been found even *worse* than some that have been kept in a dry, airy place, without being limed; while those left in the ground, and covered with an additional quantity of earth, intended to keep them all winter in the soil, are found with the *rot* still alarmingly increasing. The only remedy to prevent the disease from further increase in the tubers already affected, is, we are convinced, to keep them dry. For this purpose, we have seen some laid for some time above and over, and then stored by in a *dry, airy place.* When so treated, the disease, if increasing, goes on then very slowly. Many different opinions are prevailing as to the nature and cause of this disease; but it seems to some very glaringly to be the same dreadful epidemic that lately raged in spring—the same visitor, only come at another season. In consequence of the frequency of the disease in spring, the potatoes have become so weakened, that now, as soon as ripe, the disease appears; as it has been observed that in late situations it is longer in making its appearance than in early soils and situations. The vital juice of the potato seems lost; and this useful esculent will, it is the opinion of many, soon be unknown in our isle. A similar disease has, by some farmers here, been discovered among the turnips.

Roxburghshire.—That sort denominated the "old black potato," is universally the most affected, and seems to be threatened with extermination. They, however, are not now generally grown. Next in point of being affected are the "blues" and "buffs." An endless variety of other sorts is grown in the county, the names of which often vary in different parts; and these are all less affected than the three sorts above named. The soils in which I have observed the disease to prevail to a greater extent, are a light, turfy soil, upon a moorland bottom, and a thin, adhesive clay, upon an impervious stratum of till. This disease, like everything else, will have its proper cause, if it can be ascertained; and I am convinced that it has arisen from circumstances that can only again occur in such a season as the past. During almost the whole time that the young potato was swelling into size and advancing into ripeness, the quantity of wet in the ground, and the absence of sunshine, were peculiar; and these operating upon the potato-plant, in the tender stage of its growth, I am convinced, are the causes of the disease by which it has been affected. I am led to this conviction from the following circumstances: 1st. In narrowly watching the taking up of potatoes grown in a dry, deep loam, upon a sandy sub-soil, I observed that those which were placed in a horizontal circle round the stem, and near the surface, or partially bare, were not affected at all. 2d. Where the plants had occasionally penetrated deeper into the soil, and had produced one or more potatoes at the depth of eight or ten inches from the sur-

face, these, at that depth, were invariably affected, whilst those placed nearer to the surface, and attached to the same stem, were free of disease. 3d. In thin, turfy soils, or thin, adhesive clay, upon an impervious stratum, the potatoes were necessarily placed in a position where the wet was lodged between the soil and sub-soil; and these I invariably found to be affected. 4th. In these soils, potatoes lying close by the surface, or uncovered, were generally sound.

From the London Freeman's Journal.

FAILURE OF THE POTATO CROP.

Once more we repeat our thrice confirmed conviction, that to alternate frost and rain must be attributed the failure of the potato crop; and, of the soundness of our conclusion, we obtain abundant proof from the columns of some of our contemporaries who differ in opinion with us. Thus we find Mr. W. R. Meads, of Kinsale, stating in the "Gardeners' Chronicle" of Saturday last, that "the disease was first observed there on the evening of the 8th instant, which was a very hot day, succeeding a slight hoar frost." In the "United Gardeners' and Land Stewards' Journal," too, Mr. J. Barnes, of Bicton Gardens, Sidmouth, Devon, says: "I never felt the cold more severely in the month of March than I have done this season, during the last two weeks in July and two first weeks in August, usually most severe from half-past three to half-past four, a. m.; and I certainly never previously observed the morning frosts so severe at that season of the year." We could cite a mass of evidence to the same effect, but that would now be of little use; let us rather turn our thoughts to suggesting remedies for the evil.

In the "Dusseldorf Gazette" it is stated, that "a farmer, living on one of the estates of the Duke d'Aremberg, near Dusseldorf, has discovered a mode of preventing the rotting of potatoes, and even of curing it when it has already commenced. The method is very simple; it consists in merely harrowing deeply the earth in which the tubers are planted so as to produce an evaporation, which will diminish the fermentation caused by humidity;" and, it is added that the plan has proved completely successful. Let it be tried wherever it is not too late.

In our publication of Monday we quoted from the "Moniteur" a proposition for preserving from decay potatoes partially tainted, by a sort of semi-baking in an oven heated to 64 or 65 degrees of Reaumer, (about 180 of Fahrenheit,) and the plan, like that of converting them into fecula, or arrow-root, may answer very well on a small scale. We would recommend slicing, stringing, and hanging them in kitchens and outhouses, as apples are managed in America, as a means of saving a part of the crop, in addition to the two first described methods.

From the Gardeners' Chronicle, September 27.

POTATO MURRAIN.

It appears to me of some importance that naturalists should be careful to distinguish effect from cause. That minute and rapidly propa-

gating fungi have been observed on the affected potato plants, there is no reason to doubt. But when we know, from other facts, that such appear on plants after they are dead or diseased, and not when they are alive and healthy, we are justified in affirming that we are yet ignorant of the cause of the malady in question. To prevent its recurrence is what is desired; and it is worth while to try everything that may suggest itself from the consideration of any theory of the disease. It has not been ascertained whether it commences in the roots or in the leaves; and to determine this may be a difficult matter. If in the latter, it is to be feared that prevention is impossible. But it may commence in the tubers; therefore, without pretending to know the nature of the disease, or its cause, I will assume it to commence in the tubers, and offer advice accordingly. It is a well known fact that some insects reappear, after long intervals of time, in various members of the vegetable kingdom. It is not too much to affirm that some of these insects may be too minute for observation, and that this has given rise to many very improbable explanations of disease. That the most minute, as well as the largest insects, pass through several stages of existence, may be safely assumed; and also that one or more, or all of these, are passed in the earth. It is also known that insects deposite their eggs either on or near to that which is the food of the worm; and, in some cases, the worm may take up a position for its change into chrysalis, so that the fly may not have to go far for its first meal. These facts induce me to advise that it should be a constant yearly practice to wash all potatoes to be used for sets, when they are taken up, and to clear the eyes by means of a brush. This operation being done when the tubers are taken up, the eyes not having pushed, are not injured by the brush, which they would be were the operation deferred. This will clear the tubers of all eggs and chrysalids, and may be of service, while it can do no harm. G. S. MACKENZIE.

Rose Bank, Roslin, N. B.

Everything tends to confirm the opinion I previously expressed, that a certain degree of ripeness or maturity is necessary to feed the disease. Early sorts, from all reports, fall the first victims. Those upon dry, rich, well-drained soils follow; and late sorts, on cold wet soils, on hill-tops, or with north aspects, that tend to retard growth, seem for a time safe, and flatter the possessor they have escaped; but such no sooner reach the apparently required condition, than they may literally be said to wither in an hour. As a case in point: "Ambulator," in the last number, mentions being delighted with a field in full bloom. According to my view of the matter, potatoes in bloom are safe from attack. In my last communication I mentioned some of my own that passed that stage safely, within a few feet of earlier sorts reduced to a mass of putrefaction. "Ambulator's" will, no doubt, also decay; when I hope he will report progress. Salt, in culture, is no preventive. Has not the seacoast been worse affected generally?

The allotment field I mentioned as the first seat of disease was in many parts manured with fish and sea-weed, and washed by the spray. This, and the fact that the scourge first appeared on the coast to an alarming extent last year, sets the supposed influence of salt at rest. The parts affected last season were the first, by a month, to exhibit its fatal symptoms this year; a circumstance worth the attention of investigators.

JAMES MICKLE.

From the Gardeners' Chronicle and Agricultural Gazette, Oct. 4, 1845.

We do not as yet propose to return to an inquiry into the cause of the potato murrain, but shall continue to confine ourselves to a consideration of what can best be done under existing circumstances.

It is stated in a daily paper that M. Bouchardat, a French gentleman, has discovered a simple and economical process by which potatoes already attacked may be rendered fit for every domestic purpose. They are to be cut into thin slices, to be placed for thirty hours in water slightly acidulated with muriatic acid, then to be washed in pure water, and soaked 12 hours; after which they are to be dried in the sun, when they will again become white, with a healthy savor, and will keep any length of time.

We have tried this operation, and doubt its value. It is not said how much muriatic acid is to be employed; but, if making water just acid is all that is intended, then we have followed the directions exactly. The result is, that the slices become very white by the time they are taken out of the steep; but soon after they have been washed and exposed to the air to be dried, they change color, become livid, and have so uninviting an appearance that no English peasant would eat them unless pressed by actual famine. In a few days, however, the livid appearance goes off, and some of the slices become of a glittering white. This appearance is caused by the sides of the empty bleached cells in which the starch is laid, and not by the starch itself. Beneath is found a thin brown crust, and below the crust the potato seems to be exactly what it was before being plunged into the steep, or to be as livid as the surface was after the exposure to air took place. While, however, some of the slices dry in this manner, others refuse to do so, although laid on a dry board in a room heated by an Arnott's stove; and then, in fact, although placed next a window, speedily putrefy, and are attacked by mouldiness. We have, therefore, nothing to allege in favor of M. Bouchardat's process.

It appears from Galignani's Messenger, that, at the sitting of the French Institute of September 22, an immense number of communications on the disease of the potato are announced.

Amongst them, one in the name of M. Clerget, the inventor of a new process for making potato flour, was particularly mentioned. This flour is stated to be equal to nearly one-third of the entire mass—namely, 20 per cent. of the starch principle, and 10 per cent. of the bran or fibre. "His process is a scientific application of the old woman's process of mixing potatoes in the making of bread. This is well known. The potatoes are first boiled, then dried before the fire, and rubbed up with the wheat flour. M. Clerget produces the same result in the form of flour, emitting all the extraneous and useless portions of the vegetable, and providing for commerce, on a large and improved scale, a means of subsistence as cheap as it is wholesome." We do not profess to understand this account, but give it as we find it. Hereafter we shall learn from the Comptes Rendus what it really means * * * * * * * *

It is of far more importance to conduct the operation carefully. Professor Henslow obtained nearly six pounds of flour from a bushel of very bad potatoes; others, however, complain of not getting more than half the quantity. This, probably, depends entirely upon the care that is given to the rasping or crushing process. It is to be borne in mind that a potato is a mass of bladders, held together by organic force, and tolerably

tough. It is in the inside of these bladders that the starch is deposited by nature. If we could separate such bladders from one another, and could place them in a row, we should find that from 150 to 200 would come within the compass of an inch. Now it is necessary to burst or cut into all these bladders, if all the flour which the potato contains is to be extracted.

But no machinery yet thought of is capable of doing that. If, indeed, the potatoes could be placed between mill stones, yet the latter could not be set fine enough to crush every one of these extremely small bladders. There must, therefore, be some loss of flour in the operation of crushing, prepare it as we may; and of course the loss is great in proportion to the carelessness with which the grating or mashing is performed. One man will throw away a third of his flour in the midst of the pulp separated by the strainer; another, half; some more, some less; and it is to be remembered that no amount of washing will of itself separate the flour: crushing, mashing, pounding, &c., must be trusted to. It is therefore worth the consideration of the public whether the pulp should not be subjected, after the first washing, to some other operation, such as rubbing between two stones, or grinding, whereby the bladders which escaped the first process may be broken in the second.

But our space is more than exhausted, and we must for the present break off, with a renewal of our exhortation to potato growers to attend to *dryness*, above all things: *dry days* for taking up; *dry places* for storing them; *dry soil* for pitting; and every other precaution by which the *dryness* of the crop can be best secured against the dangerous months of winter.

* * * * * * * *

Amongst the many statements which have been made respecting the origin of the *potato blight*, there is perhaps not one which has been more widely spread than that which attributes its development to the use of highly azotised manure. A few words on this subject will not be unacceptable to those of our readers who are in the habit of using guano and similar strong manures. The effect which azotised manures exert on growing plants is tolerably well understood; it increases the growth of the plant, facilitating the formation of organized matter, and, provided the other constituents of vegetable food are also present, it causes a strong, vigorous, and healthy growth. Now, the substances required by plants are nearly all contained in guano; and, therefore, if light and heat are not wanting—in fact, if the weather is favorable to vegetation—there is every reason to expect that plants thus manured will become strong and healthy; there is no theoretical reason which should lead us to fear unhealthy or irregular growth.

There is no doubt that large and quickly grown plants are more liable to be attacked by any disease than such as are smaller; but the rapid growth of the former never *causes* disease—it only renders them more liable to suffer when other causes have combined to produce disease; at the same time, this tendency is much diminished by the superior vital energy of the larger and more vigorous plants. It is, therefore, not to be expected that plants supplied with azotised manures should be more liable to the influence of such rot as that at present common amongst potatoes, than those manured with farm-yard dung, or not manured at all; and this indeed is the truth, for so far from those plants only being attacked which were strongly manured, it appears that those which received no kind of manure at all are quite as much subject to the disease as those more highly manured with guano.

E.

In both kinds, the sound potatoes were always at the most remote point from the haulm, the bad ones being invariably just at the bottom of it; and the ends of the tubers, which seemed to be the first affected, in very many instances were also those ends attached to the haulm, while the crowns remained sound and good. This seems to me to be pretty conclusive evidence that the disease has been first generated in the haulm, and not in the tuber, and has been invariably transmitted downwards by the elaborated sap. Many of the reds were quite rotten, the inside having become a brown pulpy semi-fluid mass. But in the bread-fruits, this was seldom the case, the disease being confined either to the haulm end or to a circle running all round the outer edge of the whole potato, or merely to a few isolated patches, so that in most tubers there will be a sound heart, which will afford food for pigs, if good for nothing else. Our geological stratum is chalk, which insures of itself good drainage. Field potatoes are said to be better than garden ones here generally.

LEATHERHEAD. W. H.

I first dug the ash-leaved and Shaws about the 20th of June—the former in black mould and the latter in stiff loam—at which time there was no appearance of disease; but at the end of July, from the same places I found the potatoes diseased.

The cause, therefore, whatever it may be, did not apparently exist till the middle of July; and that moisture is either the cause, or medium, is, I think, certain, for this has been, from early in June, a decidedly wet season. The red and pink-eyed potatoes are the least affected, which I attribute to their possessing a large portion of farina, which does not decompose readily, preserving its character even in frosted tubers. In these I have not more than one-fiftieth bad, but in the early kinds one-half are affected. The latter average from five to eight lbs. of farina to the half cwt., but the former sorts yield fourteen or sixteen lbs.; showing, as regards nutriment, their great superiority. In early sorts the farina is not fully developed, being fibrous and watery, and the tubers are not so wholesome as when two-thirds grown.

The affected potato cannot be cured; and I believe the soil is not capable, from having once grown them, of producing the disease next season; and that the chlorides and other purifiers are so far useless. There is a great difference of opinion as to the cause of this calamity. I attribute it wholly to electrical agency. During the summer the atmosphere has been very much charged with electric fluid, and the moist state of the skin of the haulm acting as a powerful conductor, conveyed the fluid to the roots, and in its passage over the surface, and from thence to the next best conductor—probably another potato—it has produced the appearances which we perceive. The skin and tissue at the surface of the potato (but not the farina) loses vitality from the conducting power of the watery state, and is decomposed by the electric fluid; and which effect is probably increased when a ready conductor is not at hand. Upon this principle, potatoes grown on stiff soil, on clay bottom, will turn out the worst; and on gravelly or other porous soils, freer from disease.

Where first attacked, vitality is nearly destroyed by the sap being changed in character, and obstructed in its passage through the vessels; the leaves

and haulm become, as is usual in autumn, yellow, but from a different cause, and fungus may or may not generate itself in consequence of this premature decay.

Some of Professor Morren's observations I think are wrong. He ascribes the disease to dampness and cold air. A damp summer of itself is congenial to the growth of the potato; and when well moulded up, cold air cannot affect it. Besides, I find potatoes lying on the surface (and consequently green) not attacked at all, the air, as it were, "case-hardening" them; and these potatoes are not attacked with insects, but the wire-worms, &c., if there are any, very much infest the diseased tubers.

I should say the potatoes cease to grow, when first attacked, from the absorbents, which take up and afford them nutrition, being destroyed. I am told by a friend at Wantage, in Berks, that several old farmers spoke of seeing "white rain" fall during August, and expected unfavorable effects from it. What this white rain may have been I cannot tell, but blight has been very prevalent; and, as I before observed, an undue electric state of the atmosphere has also been prevalent. About 16 years ago I published, in the "Mechanics' Magazine," the method, as practised by me, of obtaining potato flour—its valuable uses, particularly in fattening pigs; and the valuable application of the residue of the root, when boiled, for previously feeding the store pigs with. Pigs fed only upon potatoes thus managed will fatten fast, and make fine pork.

ENFIELD. G. L SMART.

—

POTATOES IN IRELAND.

The ravages of the potato murrain have not appeared here yet; but there has been a disease in this locality for the last three or four years, which has done much mischief. Instead of commencing above ground, it seems to commence with the decay of the old set.

The tubers, as soon as they are formed, are attacked with dark colored ulcerated blotches, which soon spread over the whole tuber, and end in putrefaction; meanwhile the plant becomes languid, the leaves have a sickly yellow color, yet the plant still exists and forms more tubers, which are also attacked and carried off; the plant becoming more and more unhealthy, most frequently dies a month or six weeks before the healthy plants arrive at maturity. Nor does the evil rest here. Such tubers as escape the ravages of the disease in summer are attacked, after they are dug, during the whole winter, so that before the planting season again arrives the stock is in many cases completely destroyed.

The disease is quite local. It is not beyond six or eight miles from here in any direction.

Various remedies have been tried, such as having sets from a great distance; planting in drills instead of beds, (which is the common mode of planting here;) planting in ground which has not been broken up for a long time; planting very thinly, &c.; but almost all the trials have been attended with failure. One method, however, so far as it has been tried, seems to remedy the evil; that is, greening or sunning the sets. For the last two years those planted in the garden have undergone that process, and there has been no failure. Previously they were as much diseased in

the garden as in the field. The experiment has been tried this season in the field; and, from a partial examination, seems to have answered equally well. But the crop will be dug in a day or two, when you shall know the result. Enclosed are some diseased stems, with the late growth of tubers attached.

T. P. ELLIOT.

FLORENCE COURT.

[We are sorry to add that this disease is our English murrain, in a mild form.]

POTATOES AND SALT.

In a late number you inquire whether any one has used salt in planting potatoes. I have done this; but it may not be uninteresting to know that I dressed three half acres of newly and well drained peaty meadow first before breaking up for potatoes, and which were equally well worked and manured afterwards, as will be seen by the following statement:

No.	Lime.	Salt.	When planted.	Kind of potato.
1	5 one-horse cart loads.	3 Winchester bushels.	April 24 & 25.	1st, early; 2d, early; 3d, Highland, early.
2	Do	-	April 25 -	1st, strawberry, late; 2d, orange, early.
3	-	Do	May 1 -	1st, purple kidney, late; 2d, Highland, early.

The lime and salt were ploughed in immediately (January 11th) after the salt was sown. No. 1, all tops, except first early—gone long ago, but apparently from frost. Tops of 1st early all killed night of September 22. I find no tubers affected yet, but a mouldiness is to be seen on the haulm of many. No. 2, ditto; No. 3, far more of the mould, and a worse appearance. The potatoes in my garden (very dry sand) much as No. 1.

A CONSTANT READER.

From the observations I have made in this neighborhood, I am inclined to think that the saline properties of the sea-air do not prevent the disease, as some fields in the immediate vicinity of the sea have partially, and some have completely, failed; others are at the present time looking quite healthy in the haulm, and the tubers but little, if at all, affected. Now, does it not appear probable, that if the sea-air had any influence on the prevailing malady, it would have been more general in its effects; at any rate on those similarly situated? The sea-girt island of Jersey gives a strong proof of the non-effect of the saline air on this malady. And again, with regard to the effect salt has had, when applied to the potato at the time of planting: a patch of ground in my garden was planted in the early part of May, in the

following manner: The rows were opened with the spade about 4 inches deep; the sets were then placed in the bottom of the trench; the first lot was covered with refuse manure, the second with lime in a half slacked state, the third had a moderate quantity of salt sprinkled over the sets, and the fourth was covered with long fresh cut grass. They all came up about the same time, and were very strong in the haulm till within the last fortnight, when the tops began to die away very rapidly, and they were all cut off about a week since. The tubers have just been lifted, and I find the result, with regard to the murrain, to be as follows: Those manured with refuse dung were affected, as near as I can judge, to about 5 per cent.; those with lime, 10 per cent.; those with salt, about the same as the first; and those covered with fresh cut grass, I do not think the loss amounts to one per cent.

The potatoes, a pale red kidney; they go here by the name of *farmers.* The soil light, resting on a mixed sub-soil, consisting of gravel and clay.

G. S. H.

Glamorganshire.

—

I have about one acre of garden ground about half planted with potatoes, and it is situated within the reach of the spray of the sea, and abundantly manured with sea-weed. The result is as follows: First, my ash kidneys, planted in November in very light soil, are very little affected; Cornish kidneys, planted in December in light soil, are more than half affected; pink frame, in clay soil, about one-third affected; early Shaw, in clay soil, a total failure; Chapman's kidney, planted in June and July, (some in clay soil and some in very light soil,) two parts out of three affected. All the above were planted after the spade, and covered with sea-weed. I have about two rods of Chapman's kidney, planted as late as the 6th August, which have been looking remarkably green and well until within the last fortnight, but they are now completely cut off with the disease; so seaweed has not given me any protection whatever.

JAMES WOOD.

Harwich, Essex.

—

This parish extends along the shores of Mount's bay, and consequently a constant deposite of saline particles is going on, more especially when we have heavy gales from the south. Sea-weed is also very extensively used as a manure for potatoes, and also the beach sand.

The result of extensive inquiries has shown that no parish in our neighborhood has suffered to an equal extent with ourselves. We must, therefore, admit the conclusion that the application of salt, at least by nature, has not proved any preventive of the terrible scourge.

W. W. WINGFIELD.

Penzance.

—

I have made a circuit of several miles around this place, (Teignmouth,) and have found only one instance, with the exception of my own

crop, where the potatoes are not affected with the murrain inland, as well as on the very top of the sea cliffs. In a field where I found they were not diseased, I inquired what manure had been used, and the reply was, fresh sea-weed.

My own crop is planted on a high exposed hill, in a light gravelly soil, on a sub-soil of sharp gravel. The manure I used was one load stable dung, two loads of ashes of burnt weeds, two cwt. guano, and two cwt. salt per acre, mixed together, and sown in the furrows 30 inches apart, before planting the sets, the greater number of which were whole potatoes. I was informed that I should have very poor, watery, close potatoes, because always when salt or guano was used they were sure to be so, and, as I had used both, they would be very bad; but, instead of being so, I never had better potatoes—when dressed, they are like balls of flour.

COURTENAY M. KINGDON.

From the Gardeners' Chronicle, Oct. 11, 1845.

POTATO BLIGHT.

You have given us ample proof of the specific nature of the potato blight, and of its origin in obvious atmospheric causes, and every one must be struck with its analogy to the epidemic diseases of cattle, and the influenza like maladies of human beings. This analogy holds good in various aspects: its uniform character; its universality; its sudden invasion in various points at the same time; and its greater or less intensity, as modified by local circumstances.

It seldom happens that any notable epidemic, in animal or vegetable organisms, is so clearly traceable to its causes as the potato murrain. We see, nevertheless, that there is a diversity of opinion as to the share in the operation to be assigned to the several agencies. It cannot be wet alone, for much wetter summers have occurred within these few years without harm to the potato crop. It cannot be cold only, because the average temperature has certainly not fallen below the rate of districts and counties where the vegetable is always successfully cultivated; nor has there been, as your correspondents observe, any remarkable development of sensible electricity. But of all the incentives to a healthy vegetation, what has been so much wanting, for the last two months of July and August, as light? not merely bright sunshine, for of that there was hardly any; but even the ordinary quantity of daylight was wanting—so dense and black was the overcast, day after day, through this long period, a time when the vegetable world is in expectation, and generally in the enjoyment, of its fullest share both of light and heat. You justly suppose that the transient warmth of June gave a predisposition to disease by imparting greater sensitiveness or excitability to the plant. Doubtless another ingredient in the mischief was the absence of the usual ground-warmth that cherishes the vegetation of a more favored season. There is every reason to believe that the calorific rays penetrate the clouds and impinge on the soil, where the general diffusion of sunlight is not correspondingly powerful. Every practical gardener will observe that, at the end of even a very dull day in the middle of summer, the temperature of the soil on the surface far exceeds the warmth of the air, and even surprises him by its excess over the temperature of the same

soil in the morning. It will be said that in a dull day there is less radiation from the surface than in a clear one, and thence the accumulated warmth. It may be doubted if the difference in the ratio of light and warmth, as transmitted through a cloudy atmosphere, can be so accounted for, and the subject requires further investigation.

Were it not for this aptitude to receive the warmth of the sun, in the absence of the strong light of that luminary, it must be supposed that the soil must have been far below the average warmth during the past summer; so far as to be productive of still more extensive mischief than has yet accrued from it. But this article has already extended beyond its proper limits. The intention of the writer was to point out the propriety of greater accuracy in the application of the generic term "blight" than is usually practised, and not to swell the already voluminous discussion about the potato murrain; and, although the extraordinary absence of sunlight has been spoken of, it is not to be supposed that this has been the sole deficiency. There is abundant evidence of accumulated causes both of the primatic and repletive kinds; and potatoes die as animals do, by cold and starvation; some by decline and slow decay; others by mortification and sudden death.

* *

POTATO JELLY.

Independently of any consideration of what may be the uses to which the extraction of starch from bad potatoes may be put by the poor, under present circumstances, it seems to me not unlikely that your agitation of this question may lead to the general adoption of this substance in all families as a useful and important article of our domestic economy. The readiness with which a good sized basin full of thick jelly may be procured from a single moderate sized potato, is a fact worth knowing. I have several times repeated the experiment, and find that it does not require more than eight minutes to change a raw potato into a basin full of most excellent jelly, which has only to be seasoned with a little sugar, nutmeg, and white wine, to please the most fastidious palate. To obtain this jelly in perfection, let a potato be washed, peeled, and grated; throw the pulp, thus produced, into a jug of water, and stir it well. Pass the mixture of pulp and water over a sieve, and collect the water which passes through into a basin. Let this stand for a few minutes, and a sufficient quantity of starch will have fallen for the purpose required. Pour off the water, and then keep stirring up the starch at the bottom of the basin, while boiling water is being poured upon it; and it will soon and suddenly pass to the state of jelly. The only nicety required is to be careful that the water is absolutely boiling, otherwise the change will not take place. Mr. Darwin has recorded an instance of some of his attendants being unable to boil potatoes above a certain height on the Cordilleras, owing to the diminution of pressure not allowing the water to become sufficiently heated before it boiled. There may possibly be some connexion between the conditions under which potatoes can be boiled and their starch converted into jelly. Upon comparing this jelly with that from the starch called arrow-root, and obtained direct from Bermuda, I find a difficulty in my own person in discriminating between their flavor; though an invalid, in the habit of eating arrow-root, at once detected which was which. The difference,

however, becomes more sensible when both jellies are made palatable with sugar, &c.; for then both the invalid, myself, and another person were equally decided in our preference of the jelly from the potato to that from the arrow-root—the latter possessing a rather mawkish flavor, as though it had been prepared with smoky water.

J. S. HENSLOW.

HITCHAM.

From the Gardeners' Chronicle of October 18, 1845.

POTATO MURRAIN.

I have examined hundreds from affected fields, and I have not met with one for the last month in which I could not detect this evil; and in all I have discovered the same symptoms—namely, the disease first established by means of the hilum on that end of the potato, which henceforth assumes a darker color at first, for a week or two, merely on the surface. This by degrees spreads to the eye end of the potato, and it is when established there that the chief work of destruction occurs. Shortly after this, the character of bruised flesh appears; and I need scarcely add that when that takes place, total destruction follows with great rapidity. I have not a doubt on my mind that this mildew commences with the leaf, like other mildews; and breaking up the tissue there, which in the potato is extremely delicate and watery, as compared with other mildew subjects, (such as the white thorn, or the pea,) induces the gangrene, which, finding a proper nidus all the way down the stem, descends as rapidly through the stem into the potato, the cellular tissue of the interior of which afford as ready a facility for the spread of it. I examined a bog or pit, a few hours since, in a neighbor's field. I took thence 15 potatoes, the first I met with. Out of the 15 I found only three sound, and these could not hold out a week. I had some of the same age, and in the same stage of ripeness; these I mowed down, and took up the moment I perceived the mildew beginning to descend by the stem. They have now been in a potato hole for nearly a month, and I have lost probably about one-twentieth. This I can readily account for. There were one or two patches in these in which the disease was further advanced than in the rest of the plot.

It spreads by innoculation in the pits or bogs, just as mushroom or any other spawn does.

Wherever I find a suspicious patch, there are three or four potatoes gone together—never one alone. I turned the before named yesterday, and shook among them a mixture composed of equal parts of quick-lime, charcoal dust, and mere dry sand, the sweeping of a shed. The result of this I will announce in due time. If the disease is not far advanced, I should think the causticity of lime a most likely thing to stay its ravages, whilst charcoal dust, or any burnt refuse, perfectly dry, might be useful in regard to its anticeptic properties.

R. ERRINGTON.

OULTON PARK.

In my former remarks I considered the vitality of diseased potatoes destroyed, and, as regards the power of reproducing tubers, this is probably

the case; but I am surprised to find that many are making an effort to vegetate, although the eyes are surrounded with the malady. I have eaten many of the diseased tubers boiled, with the affected parts removed, and do not find that they are different in flavor from sound potatoes. In storing reds and blues great care is required, for a casual inspection will not detect bad ones; but the disease in white sorts, if dry, is observed directly. Any sort, if sound and kept dry, will remain in good condition.

Diseased potatoes over-dried, or even baked, become softened; but I imagine if large diseased potatoes are properly pared, warm air-dried, and put into fully dried sand, they will keep sound and good for use for some months. This I intend trying with good sized ones. With me the disease is worse under orchard trees than in more open parts; but in a sixteen-acre field in this neighborhood, in which electro-culture has been tried, a large proportion is affected, but not, in my opinion, so much from the conductors placed there as from the nature of the soil, which is a strong loam, holding much moisture. The disease now prevailing is distinct from scale or dry rot, the former arising from worn out soil or bad dressing, and the latter apparently from bad management in storing. This year the upper part of the haulm has been different from the usual appearance, having brown patches on it, and being inclined to wither, while the lower part is as yet not affected, and none of these are showing flower. I still entertain the opinion that electrical agency, acting through the medium of the watery stem, has been the cause of the disease.

L. S. SMARTT.

From the Gardeners' Chronicle of 25th October, 1845.

We have to state that government has instituted an inquiry into the character and extent of the *potato disease in Ireland.* Dr. *Lyon Playfair* and *Professor Lindley* have proceeded to Ireland to assist in this inquiry, at the desire of *Sir Robert Peel.* Such an official recognition of that formidable visitation, which we had the melancholy duty of being the first to announce as having manifested itself in Ireland, (page 623, Sept. 13,) renders all further details of its progress superfluous. It matters little now whether we were right in laying the loss of the potato crop at five sixths. It is, at least, certain that the injury is of the most extensive description. We believe our estimate to have been too low; but, at any rate, no question can be entertained of the mischief being such as to excite the serious alarm of the most powerful and sagacious of European governments.

Since our last, we have received all the numbers of the "Proceedings of the Institute" up to September 22 inclusive: a pamphlet on the potato disease, by Professor Morren; some continental papers; and numerous private communications. From the mass of matter we extract what seems to be of most importance, premising that, in all practical points, we find our own views adopted by those whose opinions are more entitled to attention.

In the first place, as to the fitness of decayed potatoes for food. Upon that point there is the most positive information. That potatoes actually putrid are unfit for food, is certain. But the number of tubers at present in that state is inconsiderable; the large mass of the crop has the brown gangrene of the surface, which gradually pierces to the centre. A curious and sufficiently practical experiment as to the possibility of eating such po-

tatoes without danger, has been tried by *M. Bonjean*, of Chambery, who states, in the *Monde*, a French newspaper, (for which we are indebted to *Mr. Pigg*, of Thorpe, near Norwich,) that he has been living almost exclusively, for three consecutive days, upon bad potatoes, which had been thrown aside as refuse. *M. Bonjean* states as follows:
